THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

VOLUME XXII.

FROM NOVEMBER 9, 1888, TO MAY 3, 1889.

LONDON:
Printed and Published for the Proprietors by GEORGE TUCKER, at "THE ELECTRICIAN" Offices, 1, Salisbury-court, Fleet-street, E.C.

1889.

INDEX TO "THE ELECTRICIAN."

VOL. XXII.

Leading Articles and Editorial Notes.

(In this Section LEADING ARTICLES are shown in Capitals.)

Abnormal Magnetisation, Dr. Oliver Lodge on, 183.
Allendale, Enterprising, 37.
Alternate-Current Wattmeters, 212.
AMALGAMATION OF THE TELEPHONE COMPANIES, THE, 682.
ANGLO-CONTINENTAL CABLES, THE, 592.
Arc Lamps, Prof. S. P. Thompson on, 500.
Arc Lighting, Cost of, in America, 268.
Armature, A 46ft., 1.
AURORA BOREALIS, THE, 338.
Australia, Development of Electrical Engineering in, 1.
Barnet, 156.
Battery Transformers, M. Paul Hoho on, 211.
Beam of Light, A, as a Conductor, 697.
Bell Patent Litigation, 35.
Birmingham Exhibition, The, 448, 556.
Blackpool Tramway, The, 156.
Board of Trade Inquiry, The, 609 641.
Board of Trade, The, and the Electric Lighting Companies, 211, 239, 388, 555.
BUSINESS, ELECTRICAL, IN AMERICA, 538.
Cablegrams, The Coding of, 582.
Candle-Power, Determination of, from the Current, 268.
Candle-Power of Incandescent Lamps 358.
Cape Cable, The Completion of the, 726.
CENTRAL STATION LIGHTING AND THE BOARD OF TRADE, 76.
Chelsea Electricity Supply Company, The, 95, 123.
Cheltenham, 527.
CHRISTMAS GREETINGS, 222.
City, The, Lighting of, 473.
City and Guilds Old Students' Association, The, 66.
City and Southwark Subway, The, 358, 501.
Cleveland Electric Heating Hoax, The, 327.
Compass, The, Superseded, 239.
Condensers, The Employment of, in the Distribution of Electricity, 672.
Conductivity of a Vacuum, The, 212.
Conflict of the Systems, The, in the United States, 296.
Constant-Current Regulation by means of Steam-Pressure, 422.
Continental Cables, The, 184, 448, 501, 525, 582, 611, 642.
Contract, A Singular, 725.
Copper Crisis, The, 500, 525.
Copper Wire, Deterioration of, by Electric Currents, 357.
Cowpen, The Lighting of, 156.
Death by Electricity, 213.
Deptford, Accident at, 643.
Derby, The Electric Light at, 208.
Dog-Killing Experiments, Mr. Harold P. Brown's, 35.
Dublin Corporation, The, and the Electric Lighting Scheme, 156.
Earth, The Use of, for Electric Lighting Purposes, 610.
EDISON LAMP PATENTS, THE, 458.
Edison Patent, An, 35.
Edison Patents in the States, Validity of, 326.
Edison's New Method of Potential Regulation, The, 581.
Edison-Swan Case, The, Judgment in, 447.
Edison-Swan Company, The, and the Sunbeam Lamp, 643.
Edmunds' System of Electrical Distribution, The, 95.
EIGHTEEN HUNDRED AND EIGHTY-EIGHT, 250, 278.
ELECTION OR NOMINATION? 194.
ELECTRIC LIGHTING IN THE METROPOLIS, 566.
Electric Lighting Stations in Europe, Prof. Forbes on, 500, 581.
Electric Motors, The Design of, 296.
Electric Omnibus, Mr. Radcliffe Ward's, 124, 358.
Electric Railway Subway, The Proposed, 296.
Electric Signalling for Naval Purposes, 240.
Electric Sugar, 2, 268.
ELECTRIC TRACTION, 136.
Electrical Coast Communication, 422.
Electrical Quackery, 698.
Electricity Meters, Prof. Forbes on, 325.
Electricity, Modern Views of, 1.
"ELECTRICITY, OUR DEFENCE," 14.
Electricity Supply Companies, The, and their Masters, 326.
Electrolytes, The Resistance of, 555.
Electrostatic Measurement of Potential, The, Sir Wm. Thomson on, 421.
Elieson Company, The, 727.
"ETHER, ELECTRICITY, AND PONDERABLE MATTER," 308.
EXHIBITIONS, THIS YEAR'S, 708.
Feeders, The Use of, 581.
Flashed Filaments, Prof. Silvanus Thompson on, 268.
Fog, The Electric Dissipation of, 267, 295.
French Dynamos, 698.
Fyfe-Main Company, The, 2.
Ganz Alternate Current Motor, The, 671.
Gas and Electricity, A Method of Reconciling, 124.
Gas Explosions, The, in the New York Conduits, 672.
Gas Interest, The Alarm of the, 2.
Geyer-Bristol Meter, The, 124.
Globular Lightning Stories, 222.
Harrow, The Lighting of, 473.
Helmholtz's Jet of Steam Experiment, 239.
Hempen-covered Submarine Cables, 422.
High Tension Currents, An Experiment with, 184.
Hookham Meter, The, 357.
Hopkinson Three-wire Patent, The Purchase of, 725.
Insulation Resistance of Installations, The, 387, 421.
International Congress of Electricians, Programme of, 155.
INTERNATIONAL ELECTRICAL CONGRESS OF 1889, THE, 166.
Ipswich, Working of the Electric Lighting Act at, 123.
Isolated Plants *v.* Central Station Service, 474.
Kensington Court Draft License, The, 1, 36.
KENSINGTON VESTRY, THE, AND THE ELECTRIC LIGHT, 400.
Lahmeyer Potential Regulator, The, 581.
Lead-covered Cables, The Durability of, 555, 697.
Leamington, 296.
Leyden Jar Discharges, Dr. Oliver Lodge on, 499, 525
Light without Heat, Prof. Brackett on, 357.
Lightning Conductors, Dr. Lodge on, 726
Lightning Conductors, Observational, 2, 641.
LITIGATION AND ARBITRATION, 432.
Lodge, Dr., Remarkable Experiment of, 525.
London Chamber of Commerce, Annual Report of the, 557.
London Chamber of Commerce, The Electrical Section of, 582, 610, 641.
Low-reading Commercial Voltmeter, Prof. Ayrton's, 474.
Magnetic Action of Displacement Currents in a Dielectric, The, 499.
Magnetisation of Iron, Action of Light upon the, 555.
Maxwell's Theory, A Crucial Test of the Truth of, 525.
Measurement of "e," The, 448.
Mendacity, Physical Science a Cure for, 67.
Metropolitan Electric Supply Company, The, 36, 557.
Mining and General Electric Light Company, The, 97.
Mining World, The, Electrical Knowledge in, 3.
Morse Instrument, An Improved, 500.
"Municipal Review," The, and Electric Light Contractors, 240.
"NATURE" ON "PRACTICAL MEN AND ELECTRICAL UNITS," 654.
Northfleet, The Series Line at, 526.
Ohm Memorial, The, 448.
OURSELVES, 15.
Overhead Wires, 211, 325, 725.
OVERHEAD WIRES FOR ELECTRIC LIGHTING, 46.
PACIFIC CABLE CONFERENCE, THE, 106.
Pacific Cable Scheme, The, 35, 65.
Paddington Vestry, The, Prof. Forbes' Report to, 641.
Paddington Vestry, The, Mr. Mackie's Report to, 183.
Paris Municipality, The, and the Electric Light, 556.
PARLIAMENT AND THE TELEGRAPHS, 622.
Patent Laws of the United States, The, 388.
Patey, Mr. C. H. B., Death of, 583.
Patten System of Multiplex Telegraphy, 422.
Phonopore, The, 582.
Photographic Study of Self Induction, The, 388.
Piccadilly, A Power-station near, 725.
Popp's, M., Scheme of Electrical Distribution, 556.
Practical Standard of Light, A, 267.
Quartz as an Insulator, 673.
Race Meetings and Telegraphy, 698.
Rates to the Continent, The New, 611, 642.
Reporters, Exclusion of, at the Institution, 325.
Rowlands', Prof., Experiment on the Magnetic Effect of Convection Currents, 155.
Secondary Batteries, The Electrolyte used in, 726.
Sewage, The Electrolytic Treatment of, 583.
Sheffield, Successful Central Station at, 184.
Shelford Bidwell, Mr., on the Election of Council, 825.
Silver, The Electro-Chemical Equivalent of, 698.
SOCIETY OF ARTS TRIALS OF MOTORS FOR ELECTRIC LIGHTING, THE, 484.
Society of Telegraph Engineers, The Council of, 123, 155.
Sodium, Metallic, Economical Production of, 97.
South Africa, Telegraphic Communication with, 473.
Southwark Bridge Station, The, 326.
Sprague, Mr., and Mr. Albion T. Snell, 66.
St. John's Colliery, The Electric Pumping Plant at, 2.
Standard Types of Electrical Apparatus, 387.
Standardising Laboratory, A, 267.
Standardising Laboratory at Grenelle, The, 725.
Storage Batteries, Mr. Preece on, 96.
Storage Battery Patent Decision in the States, 643.
Storage Batteries for Street Cars, 65, 124.
Supply Companies and the Electric Lighting Act, 123.
Systems of Scientific Units of Measurement, Mr. F. H. Blakesley on, 447.
Tanning, Electricity applied to, 474, 671.
Technical Education, 36.
Telephone Amalgamation, 556, 642, 697.
Telephone Amalgamation, 725.
Telephone Circuits and High Tension Currents, 184.
Telephone Convention, The Proposed, 556.
Telephone, The, as an Adjunct to the Confessional, 156.
Ten Thousand Volts at the Grosvenor Gallery Station, 1.
Tesla Motor, The, 95.
Third Brush Regulation, 183.
Thomson's, Sir William, Inaugural Address, 239, 295.
Tin-plating by Electricity, 727.
TRANSFORMER PATENTS, THE GAULARD-GIBBS AND THE JABLOCHKOFF, 510.
Transformer, Prof. Elihu Thomson's New, 698.
Trotter, Mr. A. P., Appointment of, as Secretary to the Electrical Section, 641.
UNDERGROUND CONDUITS, 738.
Underground Conduits and Electrical Conductors, 609.
UNDERGROUND WIRES IN NEW YORK, 370.
Underground Wires, Report on, 526.
Unit of Electrical Supply, The Proposed Alteration of, 65.
West Brompton Station, The, 358.
Westinghouse Company, The, and its Technical Officers, 66.

(RECAP) 241075 = cop. 2

Foreign Correspondence.

AMERICAN NOTES.

Accumulator Patent Decision, An Important, 632.
Acheson, Mr. E. G., on the "Alternative Path," 377.
American Bell Telephone Company, The, 202, 258, 519, 691.
American Electrical Patents during 1888, 465.
American Gas Light Association, The, Meeting at Toronto, 82.
American Inventions at the Paris Exhibition, 465.
American Street Railway Association Convention, The, 20.
Atlantic City, The Sprague Road at, 439.
Baseball by Telegraph, 53.
Bell Telephone Monopoly, The, Probable Extension of, 519.
Bentley-Knight System, The, 52, 347.
Bishop Cables, 346.
Boston, Electric Light Agitation in, 228.
Boston, Proposed Subway System for, 53.
Burke Cable Relay, The, 576.
"C. and C." Motor Company, the, Important Experiment by, 376, 439, 492.
Carbon Brushes for Motors, 575.
Chicago, Electric Lighthouse at, 258
Chicago Opera House, Wiring of the, 377.
Copper Crisis, The, 633.
Copper Ring, The, 284.
Edison Chemical Meter, The, 258.
Edison Convention at Kansas City, 518.
Edison Dynamos for Marine Work, 690.
Edison Interests, The, Consolidation of, 258, 283, 347.
Edison's Laboratory, 720.
Edison Patents, The, 410, 439, 575, 600.
Edison Plant for 80,000 Lamps at Chicago, 518.
Edison's Talking Daily Paper, 203.
Edison "Up-Town" Stations, The, Opening of, 316.
Electric Light Consolidations, 662.
Electric Railway Activity, 575, 690, 719.
Electric Railway Development in 1888, 377.
Electric Railways, Overhead Wires for, 601.
Electric Sugar Fraud, The, 346.
Electric Welding, 22, 576, 633.
Electrical Subways, The, 52, 116, 171, 203, 575, 690, 719.
Electricity and the Monthly Magazines, 720.
Electricity applied to Mining, Mr. T. W. Sprague on, 53.
Electricity, Death by, 115, 228, 317, 575, 601.
Elevated Railways, The, Daft Electric Locomotive on, 170, 492.
Gas and Electricity, 632.
Geyer Meter, The, 116.
Great War Syndicate, The, 258.
Jacksonville Electricians, The, and the Yellow Fever, 83.
Julien Car, Working of a, 749.
Lightning, Dr. M. G. Parker on, 116.
Los Angeles, The Electric Railway at, 285.
Marine Work, Edison Dynamos for, 690.
Methods of Artificial Illumination, Efficiency of, 601.
Modern Views with respect to Electric Currents, 575.
Montreal, Telephone Rate War at, 83.
Montreal, Utilisation of the Lachine Rapids at, 146.
Municipal Electric Lighting, 632.
National Electric Light Association at Chicago, 518.
New York, Growth of Electric Lighting in, 203.
Niagara, Plans for Utilising the Water-power of, 466.
Omaha, The Electric Railway at, 146.
Overhead Wire Agitation, The, 749.
Patten System of Multiplex Telegraphy, 519.
Phonographic and Telephonic Experiments, 491.
Pillsbury Flour Mills, The, Electric Light at, 518.
Revival of Electric Lighting in England, The, 82.
Roberts' Primary Battery, 284.
Sprague System, The, 21, 146, 439, 547.
Stock Tickers and their Patrons, 229.
Storage Battery Cars, 229.
Storage Battery Decision, Important, 660.
Storage Battery Patents, The, 749.
Telautograph, The, 203.
Telegraph, The American Press and the, 283.
Telegraphers' Mutual Benefit Association, The, 171.
Telephone Companies, The, and the State Legislatures, 601.
Telephone Companies, The, and the Presidential Election, 83.
Telephone Litigation, 52, 114, 228, 492.
Telephone Rates, The Agitation for the Reduction of, 410.
Telephone, The, and the Life-Saving Service, 171.
Thomson Transformer, The New, 719.
Thomson Welding System, The, 576, 633.
Thomson-Houston Electric Company, 633.
Thomson-Houston Electric Railroads, 21, 83, 146.
Tesla Motor, The, 21.
Topeka (Kansas), The Electric Railway at, 83.
Train Lighting by Electricity, 410, 575.
United States Illuminating Company v. The Board of Electrical Control, 317.
Washington, The Electric Railway at, 21.
West Indian Cables, 346.
West Indies, The, and South America, American Enterprise in 146.
West Side Electric Light Company, The, and the Board of Electrical Control, 749.
'Western Electrician," The, on the Combination of Conflicting Interests, 284.
Western Union Company, The, and the Board of Electrical Control, 748.
Western Union Telegraph Company, The, 202, 258, 317, 633.
Westinghouse Electric Company, The, 21, 53, 115, 203, 410, 547.
Weston's, Mr. E., Measuring Instruments, 115.
Woodward Storage Battery, The, 633.

BRUSSELS NOTES.

Brussels Exhibition, The, List of Awards, 53.
Brussels Municipality, The, and the Thomson-Houston Company, 466.
Brussels, The Electric Lighting of, 347, 548.
Central Hotel, The Lighting of, 260.
Electric Signalling Apparatus for Night Watchmen, 260.
"Etoile Belge," The, Enterprise of, 260.
Gare du Nord, The Installation at, 53.
Ghent, An Installation at, 259.
Houillères-Unies, The Electric Light at, 548.
Lalaing Electric Light Mast, The, 467.
Liége, M. Tudor's Proposals at, 467.
Luxembourg, Grand Duchy of, Electrical Enterprise in, 53.
Mourlon Frères, MM., Formation of, into a Company, 260.
Schanschieff Battery, The, in Belgium, 467.
Syndicat, An Electrical, 259.

GERMAN NOTES.

Allgemeine Elektricitäts Gesellschaft, The, 691.
Barmen Central Station, The, 411.
Berlin Central Stations, The, 411.
Bremen Central Station, The, 411.
Darmstadt Central Station, The, 411.
Elberfeld Central Stations, The, 519.
Electric Motors in Germany, The Manufacture of, 691.
Frankfort, Transformer Plant at, 519.
Fritsche and Pischon's New Wheel Armature Dynamo, 519.
Germany, The Past Year in, 411.
Hamburg Central Station, The, 411.
Nuremberg Railway Station, The Installation at, 519.
Prize of 1,000 Marks, A, 519.
Transmission of Power by Alternating Currents, The 411.

PARIS NOTES.

Amiens, Central Station at, 663.
Bechmann, M., and the Illuminated Fountains at the Exhibition, 663.
Bon Marché, The Lighting of, 548.
Boulevards, The Lighting of the, 662.
Champs-de-Mars, The Provisional Installation on the 662.
Conseil Municipal, The Authorisations of, 259, 547.
Gas Companies, The, and the Electric Light, 662.
"Gymnote," The, 259.
Halles Centrales, Lighting of the, 22, 259, 663.
Heroult Process in France, The, 548.
Left Bank of the Seine, The Lighting of, 663.
Palais-Royal Central Station, The, 22, 259, 347.
Popp, M., on Electric Lighting in Paris, 466.
Société des Métaux, The Fall in the Shares of, 547.
Syndicat International des Electriciens, The Tariff of, 22.
Telegraph Lines, The, and the Snowstorms, 466.
Telephones, The Government and the, 663.
Thomson-Houston System in Paris, The, 347.
Vaucluse, the Asylum at, Lighting of, 663.

SCANDINAVIAN NOTES.

Copenhagen Corporation and the Telephone Company, 576.
Copenhagen, The Electric Light at, 23.
Electric Cable Factory, A Swedish, 576.
Electric Light in Diving Operations, The, 172.
Eriksson Microphone, The New, 576.
Helsingborg, The Electric Light at, 172.
Incandescent Lamp Factory, A Large, 412.
Railway Carriages, The Electric Light in, 412.
Stockholm General Telephone Company, The, and the State Telegraphs, 172.
Stockholm, New Central Station at, 22, 412.
Stockholm Telephone Company, The, Statistics of, 412.
Sundsvall, Electric Tramways at, 412.
Sweden, Electric Lighting Progress in, 23.
Sweden, Inland Telegrams in, 576.
Tanning, Electricity applied to, 23.
Telegraph Rates in Sweden, 23.
Vesteras Central Station, The, 172.

VIENNA NOTES.

Crown Prince Rudolf, The, and the Vienna Electrotechnical Society, 467.
Electric Lighting Activity in Austria, 548.
Houses of Parliament, Lighting of the, 172.
Marienbad, Electricity at, 285.
Passion Plays by Electric Light, 285.
Schenken Strasse Station, The, 172, 285.
Telegraphic Development in Austria, 548.
Telephonic Progress in Austria, 172, 601.
Vienna Telephone Company, The, 467, 749.
Werndl, Mr., Death of, 749.

Letters to the Editor.

Albion Gas Engine, The ..... G. T. P., 320.
Alkaline Accumulators ..... Greville, A. E., 350.
Coates, H. J., 350, 413.
Elwell, P. Bedford, 378.
Beaumont, W. Worby, 378.
Alternating Currents ..... Brown, H. P., 55.
Arc Lamps for Amateurs ..... Bouquet, R. P., 750.
Aurora Borealis, The ..... Mordey, W. M., 379.
Bank of England, The Electric Light at the .. Drake and Gorham, 57.
Barnet Electric Light, *Re* ..... Joel (H. F.) and Co., 25.
Bath, The Invasion of, by the House-to-House Company ..... Massingham, H. G., 280, 351.
Winkworth, H. St. John, 319.
"Disinterested Observer, A," 351.
"Marsden," 351.
Battery Transformers and the Vienna Installation ..... Crompton, R. E., 202.
Ben Nevis, Electric Effects on ..... Lodge, Dr. O. J. (with letter from Omond, R. T.), 205.
Berlin Cables, The ..... Sayers, W. B., 692.
Berners-street Mishap, The ..... Higgins, F., 231.
Bleaching, Electric ..... Andreoli, E., 494.
Cable Testing ..... "Megohm," 86.
Bright, Charles, 148.
Central Lighting Stations of France, The..... Ganz és Társa, 602.
Condition of Alloys and Solid Sulphides, The.. Hibbert, W., 149.
Copper, The Standard Conductivity of ..... Higgins, F., 117.
C. J. S., 149.
Davey-Paxman Engine Trials, The ..... Hartnell, Wilson, 548.
Defence, Electrical ..... Zalinski, E. L., 261.
Deflection of an Electro-Magnetic Wave by Motion of the Medium ..... Heaviside, Oliver, 663.
Designing of Continuous-Current Dynamo Machines, The ..... Geipel, W., 549.
Jamieson, Prof. A., 577.
Disclaimer, A ..... Gill (Arthur B.) and Co., 497.
Dr. Lodge's Experiments ..... "Ignoramus," 749.
Durtnall *v.* Shippey ..... Tadd, John, 692.
Edmunds', Mr., Method of Maintaining Constant Current ..... Bate, Douglas C., 379, 412.
Edmunds, H., 349.
Neville, R. H. C., 349.
Bernstein, Alexander, 379.
Smith (John) and Co., 443.
Education of Electrical Engineers, The ..... Day, Gerald, 720.
Effect of Current upon Conductors, The ..... Bartlett, A. T., 440.
Yeaman, Charles H., 468.
Electric Lighting Companies at Kensington and West Brompton..... Erskine, R. S., 495.
Winkworth, H. St. John, 520.
Electric Lighting of Schools ..... Ryder, Thos., 174.
Electrical Theory ..... Fitzgerald, G. F., 24.
Thompson, Silvanus P., 54.
Heaviside, Oliver, 83.
Hutchinson, Cary S., 173.
Lodge, Dr. O. J., 204.
Electro-Calorimetry ..... Eversheld, Sydney, 24.
Electrolysis, Theory of, An Experiment in the, by Prof. Ostwald ..... Lodge, Dr. O. J., 493 (with Ostwald, Prof. W., and Ramsay, Prof.), 691.
Brown, J. 676.
Electro-Magnetic Effect of a Moving Charge .. Heaviside, Oliver, 83, 147.
Electro-Magnetic Waves and the Propagation of Potential..... Heaviside, Oliver, 23.

Letters to the Editor (*continued*).

Electrometer, Blondlot and Curie's	ATKINSON, LLEWELLYN B., 261. WILBERFORCE, L. R., 207.
"Elements of Electric Lighting"	ATKINSON, PHILIP, 231.
Elmore's Electro-Burnishing Process	ROUX, GASTON, 148, 205. C. J. S., 173.
Enamel as an Insulator	F. H., 520.
Ether, The	GRANVILLE, W. P., 24.
"Ether"	CARTER, E. T., 351. THOMPSON, N. G., 379.
"Ether, Electricity and Ponderable Matter"	ROSS, O. C. D., 380.
Experimental Lightning Conductors	LODGE, Dr. O. J., 646.
Fahrig's Influence Machine	FAHRIG, ERNST, 205.
Feeders, The Use of	HOLMES AND VAUDREY, Messrs., 634.
"First Course of Mechanical Drawing"	HALLIDAY, G., 389.
Flashed Filaments in Lamps	THOMPSON, Prof. S. P., 261.
Fog, Electrical Dissipation of	LODGE, Dr. O. J., 260, 285. BRUCE, ERIC S., 285.
Fritsche Dynamo, The	JEHL AND RUPP, Messrs., 602.
Galway, The Electric Light at	GALWAY ELECTRIC COMPANY, THE, 288
Gaulard, M. Lucien, The Death of	CADIOT, E. H., 147.
Geyer-Bristol Ammeter, The	JOYCE, SAMUEL, Jun., 174.
Glasgow City Hall Lighting	G. T. P., 263.
Globular Lightning	WORDINGHAM, C. H., 56. J. H., 117. MOORSEL, J. VAN, 520. FAHRIG, ERNST, 413. EVERSHED, SYDNEY, 443. COWAN, EDWARD W., 720.
Harrow, The Lighting of	CROMPTON, R. E., 494.
Hempen-Covered Cables	LUGAR, W. R., 468.
Hookham's Electricity Meter	HOOKHAM, GEORGE, 413.
Injunction against the Julien Company, The	DELL, H., 750.
Institution of Electrical Engineers, The	BIDWELL, SHELFORD, 318. PROVINCIAL MEMBER, A, 380.
Kensington Vestry Report, The	ERSKINE, R. S., 495.
Kimberley, The Lighting of	STATTER (J. G.) AND CO., 320.
Lahmeyer's System of Regulation	HOUSMAN, R. H., 750.
Light without Heat	WORTH, A. B., 412.
Lightning Conductors	FORSTER, W. G., 441.
Magnetic Effect, The, of Convection and Displacement Currents	HUTCHINSON, CARY S., 173.
Magnetization of Soft Iron	EVERSHED, SYDNEY, 24.
Magnetism of Steel Needles, The, by Leyden Jar Discharges	LODGE, Dr. O. J., 204.
Mance's Battery Resistance Test	HIPPISLEY, Capt. R. L., 634.
Meters, Electricity	FORREST, JOHN E., 286.
Mirrors for Galvanometers	SMITH, A. B., 721.
Mœnnich Indicator, The	YEAMAN, CHARLES H., 468.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 547.—Vol. XXII. FRIDAY, NOVEMBER 9, 1888. Price 4d.

NOTES.

In the chapter on "Modern Views of Electricity," in last week's *Nature*, a very novel explanation is offered (with some reserve) to account for Faraday's experiment of the electro-magnetic rotation of the plane of polarisation. Our readers must be referred to the original Paper for the full explanation, but we may endeavour to give a brief account of the theory as applied by Dr. Oliver Lodge to that form of the experiment (due to Kerr) in which a beam of plane-polarised light is observed to be rotated when reflected from the polished pole of a magnet. This, Dr. Lodge thinks, is an effect of *hysteresis*. First, it must be remembered that undoubtedly "something in the nature of a rotation is going on in a magnetic field around the lines of force," and this rotation, even within the iron itself, we have every reason to believe takes place in the ether. Next, we have to recollect that by an elementary theorem of mechanics any rectilinear vibration in a given plane may be resolved into two equal circular components which rotate in opposite directions around the same periphery. Now, apply this to the electro-magnetic vibrations (of the ether) which constitute the ray of plane-polarised light. In the process of reflection from the polished surface of the iron the ray penetrates to an excessively minute extent into the metal. Here it meets the magnetic whirls, which are all in one direction. One of the two opposite circular components therefore tends infinitesimally to magnetise the iron more strongly, and the other infinitesimally to demagnetise it. But owing to the existence of hysteresis the value of k, or the magnetic susceptibility of the iron, which offers itself to the two components, will be different; hence they will go at different rates and the plane of vibration will be rotated.—If any of our readers are anxious to refresh their memory on the physical aspect of the Maxwellian view of the electro-magnetic field, and are unable to refer to these Papers of Dr. Oliver Lodge, we may direct them *faute de mieux* to *The Electrician* of February 11 and 25, 1887. It is, however, to be hoped that "Modern Views of Electricity" will be republished *in extenso*.

We are this week enabled, by the courtesy of the Board of Trade, to publish a copy of the draft regulations which have been drawn up by the Board in reference to the Kensington Court Electric Supply Company. It must be understood that this is merely a tentative move, and that the Board have expressed their willingness to consider any objection which may be raised on the part of the undertakers. We understand that the subject will be taken into consideration at the next meeting of the Committee of the Electrical Trades, and if any amendment be considered desirable, representations will, no doubt, be made. Although the Board are empowered to make separate and distinct regulations in respect of each station working under a license, yet it may be taken for granted that this, being the first instance of the kind, will serve as a model for all similar installations. The copy has not long been in our hands, and we therefore prefer not to express any opinion of our own for the moment.

At the Grosvenor Gallery Central Lighting Station, on Wednesday evening, and at the hour of midnight, the representatives of the technical press, having previously visited the engine and dynamo rooms (of which a full description will be found on a later page), witnessed a highly interesting experiment with a current of 10,000 volts potential. One hundred 100-volt lamps arranged *in series* were fully incandesced, affording an ocular demonstration of the presence of the 10,000 volts. A pair of copper wires, with their ends facing one another at a distance of half an inch, were then placed in the circuit, and all lamps were extinguished. The primary current being turned on, the ends of the wires were immediately seen to glow with a brush discharge, which steadily increased in brilliancy until, in about four or five seconds, the circuit was broken by the rupture of the safety fuse. The light at the points did not attain any great degree of brilliancy and bore no resemblance to an arc; the current probably did not exceed three or four amperes.

In connection with the Deptford scheme, it may be interesting to mention that arrangements will be made whereby the 46-feet dynamos may be taken to pieces, to permit of the inspection of the armature, in the space of *one and a-half minute*. For this purpose a special winding engine for separating the field-magnet is provided, as well as a barring engine for moving the armature. We understand that it is intended by this means to make a daily inspection of the machines.

In the development of electrical engineering Australia has hitherto shown itself to be even more behindhand than the mother country; but we have noted of late several encouraging signs of progress there and in New Zealand. In the report of the directors of the Australasian Electric Light Power and Storage Company we find the following sentence, to which we give prominence since it entirely accords with our own impres-

Digitized by Google

sions:—"In the meantime it is very evident that a great development of electricity in all its branches is just commencin the [Australasian] colonies, and that . . . remunerative work is to be had for a company strong enough to undertake it."

THE coal gas interest is again showing signs of uneasiness, amounting in some quarters to positive alarm; and on this occasion it may be conceded that their trepidation is not entirely groundless. The Gas Light and Coke Company have promptly followed up the announcement of the Deptford scheme by a reduction of 3d. per thousand cubic feet to all consumers north of the Thames. This means, we believe, a saving of something like £200,000 a year to the community, for which they are wholly indebted to electric lighting. One of the leading organs of the gas interest, judging from the following paragraph, seems already to have lost its senses altogether:—"It is well," says the *Gas and Water Review*, "that our readers should know what is being done. We certainly think that a general conference should be held to consider what course is to be taken in order to ensure that this creeping rival shall at least be subject to some control, and limited to some district." "Limited to some district" is excellent!

WE are very pleased to learn that the suggestion made last week in these columns to the effect that the Submarine Telegraph Companies should undertake to make observations on lightning phenomena, in accordance with the proposals of Dr. OLIVER LODGE for meteorological stations, is not unlikely to bear fruit. What is now required is a detailed plan of operations, including designs for the experimental rod or rods to be erected. During certain times of the year, at such stations as Penang and Singapore, thunderstorms are of daily occurrence, and probably more would be learnt in a few weeks than in as many years in this country.

WE have already expressed a good deal of scepticism as to the alleged process of refining sugar by electricity, over which so many people in Liverpool and Birmingham have lost their heads. (Let us hope, by the bye, that no more serious loss may ensue.) In the first issue of a new monthly journal called *Sugar* there is a paper by Mr. T. L. PATTERSON, F.C.S., in which such meagre information as has been allowed to appear is subjected to critical examination. And meagre as the published details are, enough has been disclosed to furnish a condemnation of the story. Mr. PATTERSON'S indictment amounts briefly to this:—It is stated that the process is dry throughout; but dry sugar is a non-conductor of electricity. Raw sugar consists of cane sugar intermixed with glucose and various foreign ingredients, and it is practically impossible to remove the foreign matter, such as sand, woody fibre, &c., except by solution. It is claimed that the whole of the glucose is converted into cane sugar. The chemical composition of glucose is given by the formula $C_6H_{12}O_6$, while that of sucrose is $C_{12}H_{22}O_{11}$; to turn glucose into sucrose it is therefore necessary to abstract one molecule of water. Notwithstanding the innumerable attempts which have been made to effect this transformation no practical success attended any of the earlier efforts. About two years ago it was, however, said that two French chemists had succeeded in producing a certain amount of sucrose from glucose by electrolysis; but this, of course, was in *solution*; and after all nothing came of it. Moreover, it is impossible to believe that the sucrose if formed could be re-crystallised *in the dry condition*. Lastly, Mr. Patterson examines the per centage analysis which the company has been unwise enough to give to the world, and he is able to demonstrate that if the figures are correct the electrical process must be credited with the production of about 2 per cent. more refined sugar than is contained in the raw material. If this be confirmed we shall be quite willing to admit the invaluable nature of the discovery in spite of all other objections.

WE have been pleased to learn that the Fyfe-Main Electric Lighting and Construction Company are amongst those who are very distinctly feeling the influence of the present revival in electric lighting. We say this with the more emphasis since (and it is perhaps a fact not generally known) none of the original shareholders in this company lost any of the money which they subscribed, the whole of the £60,000 of paid-up capital having been returned in full. In our last issue we somewhat inadvertently referred to this company in the same breath with certain others whose history is of a less fortunate character. It is well known that the company in question have several very successful installations at work in the Fleet-street newspaper offices, including those at the *Daily Telegraph*, the *Standard*, and the *Daily News* offices, whilst some others of the same character are now in hand. We learn also that a new street which is being built at Brixton is to be lit with 40 Fyfe-Main arc lamps. We shall shortly give further details of this installation, which is likely to prove of an interesting character.

THE United Telephone Company have just received from America a switch-board which, when fitted, will be the largest in this country, being capable of accommodating between five and six thousand subscribers. This is now the eleventh multiple board put up by the United Telephone Company, and has been acquired in order to carry out more fully the policy of centralising the exchanges which was initiated some years ago. This step will enable two additional exchanges to be closed. At one time it would have been considered necessary to close the switch-room in order to permit alterations of this kind to be made; but, as a matter of fact, the extensive series of changes which are to be made in the London service are being carried out without the subscribers becoming aware of the fact.

AT Normanton recently we had an opportunity of inspecting the electric pumping plant at St. John's Colliery, which was described in detail in our issue of March 30th. Our readers will recollect that this plant was designed by Messrs. IMMISCH AND Co. It was erected about Christmas last, and has been working since then almost continuously. The duty is about 7,000 gallons per hour raised through a height of nearly 900ft. Messrs. LOCKE AND Co. tell us that no difficulty has been

Digitized by Google

experienced with the electrical details. The pump hands have readily learned to adjust the brushes and to carry out the few simple instructions given by the makers. The plant had been indicated on the day before our arrival, and the result showed a slightly better efficiency than that obtained by Mr. Albion Snell when the plant was erected. The ratio between the theoretical value of the water delivered on the surface and the work indicated in the cylinders is about 42 per cent., which is more than double that obtained from the compressed air plant previously in use. We may add that an extensive system of electric haulage is about to be adopted in this colliery. A good deal of the plant is already on the spot, and in a few weeks' time it will probably be in working order.

At a meeting of the Rhondda Valley Colliery Officials' Association, held the other day, Mr. Beith (an electrician who attended to advocate electric traction) was asked, "*In your experience as an electrician* can you tell me whether a smaller or a larger cable gives the least loss?" Another "official" was doubtful whether the locomotive would require the same power on a level as on an incline. The discussion finally resulted in the expression of an opinion that locomotives were not likely to be of much use in mines—apparently on the ground that they might be expected, as a rule, to run off the rails. All this shows that, notwithstanding the enterprise displayed by some few colliery owners, yet a vast amount of educational work still remains to be done before the simplicity, efficiency, and reliability of the electric motor will be properly appreciated in the mining world. As another illustration of this fact we may mention a case which has recently come to our knowledge where a well-known firm offered to lay down a complete electric plant, to keep it running for three months, and if unsatisfactory, to clear it away entirely at their own expense. After the negotiations had proceeded for several months, and very considerable trouble and expense had been incurred, the proposal was finally shelved, and a compressed air plant—costing more money, and, of course, not nearly so efficient—was put in. This is, of course, not by any means a solitary instance of the difficulty of overcoming inertia with which the electric motor has to contend.

Interruption of the Trinidad-Demerara Cable.—We are informed that the cable between Trinidad and Demerara is interrupted.

Venezuelan Telegraphs.—Notice has been received of the suspension of traffic on the land lines between Caracas and La Guayra (Venezuela) and Buenaventura.

Copenhagen.—The large brewery at Karlsberg (Copenhagen) has recently been fitted with a very fine installation, comprising four 120 horse-power steam engines and two 1,000 light dynamos.

Augsburg.—The Augsburg authorities have accepted the proposal of the Allgemeine Electricitäts Gesellschaft, of Berlin, to establish a central lighting station in that town for the general supply of electricity.

Jedburgh.—Messrs. John Hilson and Son, manufacturers, have this week had the electric light introduced into the Cannongate Woollen Mills, at Jedburgh. Messrs. H. F. Joel and Co. were the contractors.

Personal.—Mr. George R. Webb (eldest son of the Secretary to the Society of Telegraph-Engineers) has sailed for Bombay, to take up his appointment as Assistant Telegraph Superintendent of the Great Indian Peninsula Railway.

The Royal Institution.—At the general monthly meeting of the Royal Institution on Monday, November 5, the special thanks of the members were recorded for Mr. L. M. Rate's donation of £50 to the fund for the Promotion of Experimental Research.

The Manchester Jubilee Exhibition.—The report of the Manchester Jubilee Exhibition, which has recently been issued, states that the total number of arc lamps employed was 512, and of incandescent 3,570, burning for 500 hours. The total cost amounted to £9,524. 9s. 10d. There were no failures of any kind.

Immisch's Electric Dog Carts and Launches.—We are pleased to learn that the electric dog cart built by Messrs. Immisch and Co. for the Sultan of Turkey has given great satisfaction. His Majesty has not only decorated Mr. Volk, the representative of the firm, but has given orders for another dog cart and an electric launch.

The Telephone in Hampshire.—The West of England and South Wales Telephone Company have now settled all preliminary details for the extension of the telephone from Portsmouth to Gosport, Fareham, Winchester, Southampton, and Bournemouth, so that the work will very shortly be taken in hand. An exchange will presently be opened in Winchester.

Gosport.—The scheme of the British Tramways and General Syndicate for running an electric tramway between Gosport, Alverstoke and Bury Cross was considered at a recent meeting of the Roads and Works Committee of the Alverstoke Local Board. The committee unanimously resolved to recommend the scheme for the sanction of the Local Board. The line will be of the three-foot gauge, and accumulators are to be used.

The Northern District Telephone Company.—The Northern District Telephone Company have opened exchanges at Wallsend-on-Tyne and Linthorpe. Exchanges will also shortly be opened in Alnwick, Berwick, Redcar, Saltburn, and Jesmond. The trunk line to Redcar and Saltburn is already constructed, and messages are daily sent from these towns over the whole of the company's system, in some cases over a distance of 90 miles.

Gillingham.—At the last meeting of the Gillingham Local Board, Mr. Mackay drew attention to the article in *The Electrician* on the new works at Deptford, with a view to eliciting information as to the terms existing between the board and the gas company. It was stated that in the event of the board being desirous of terminating their contract with the gas company no notice of such termination would be requisite.

The Lighting of the Mansion House.—At the last meeting of the City Council Mr. Judd moved "That it be referred to the General Purposes Committee to consider the best means of lighting the Mansion House by the electric light, to obtain tenders and estimates for the necessary works, and to submit them to this Court, and that for this purpose the committee be authorised to expend a sum not exceeding twenty guineas." This was agreed to.

The Kensington Vestry at Eastbourne.—The members, officials, and medical staff of the Kensington Vestry visited Eastbourne on Monday last to inspect and report upon the working of the electric light, now adopted by the Corporation for the sea-front and municipal buildings. The Mayor entertained the deputation at a public luncheon, where the enterprise of Eastbourne was highly praised. Over 1,700 electric lights are now in use in that town.

Digitized by Google

Street Lighting in London.—At a meeting of the Committee of Works of the St. George's Vestry a letter was read from the Vestry of St. James's relating to certain proposed alterations in the gas lighting of those streets which are under the joint control of these vestries. A motion was, however, carried to the effect that, in view of the recent great advances in electric lighting, the present is an inopportune time to make any alterations in the street lamps.

Dartmouth.—The West of England and South Wales Telephone Company are about to extend the telephone system which centres at Torquay to Brixham and Dartmouth. In the case of the latter town, the wire will be carried over the River Dart at a considerable elevation, so as not to interfere with the navigation, at a point where the stream is over a third of a mile in width. Newton Abbot, Totnes, St. Marychurch, and Paignton are already connected with Torquay.

The Regulation of Dynamos.—In a recent number of the *Electrotechnische Zeitschrift* there appears an article by M. Paul Müller describing a method of regulating dynamos by means of a movable core contained within hollow field-magnets. As a translation of this article has been published by one of our contemporaries it may be as well to say that, whatever may be the practical value of the device, it is already public property, having been described in a very early patent of Lontin.

Machinery and Tool Catalogue.—We have received from Messrs. Churchill and Co., of 21, Cross-street, Finsbury, a handsomely got-up catalogue of American machinery and tools, comprising all kinds of lathes, wood-working machines, twist-drills, lathe and drill chucks, milling machines, gauges, callipers, sight-feed lubricators, blowers, fans, exhausters, indicators and valves, &c., &c. Many of our readers will find it worth while to get a copy of this catalogue, which contains several novelties which have been specially selected for the English market.

Toulouse.—Owing to the enterprise of the Comte de Chanteau, Toulouse will shortly possess a fine central lighting station. The plant will comprise 8,330 horse-power turbines, 4,330 horse-power steam-engines, and the necessary number of boilers. Each turbine and steam-engine will drive direct a couple of continuous-current dynamos, each absorbing 160 horse-power, and running at 250 revolutions a minute. The current generated by the hydraulic plant will be utilised by day for electrolytic purposes. The firms of A. Pinguely, of Lyons, and P. Blanchot and Co., of Vevey, are the contractors.

Brussels Exhibition Awards.—The jury of the Brussels Exhibition have just made their awards, and we are pleased to learn that the Electrical Power Storage Company has been awarded a gold medal. All the electrical firms which have taken part in the lighting of the exhibition have been given *diplômes d'honneur*. In addition to this gold medals have been awarded to MM. Mourlon Frères, Pieper, Bouckaert, as well as to the Phœnix and Industrielle Companies. Silver medals have been obtained by MM. Schubart, Raikem, Van der Plassche, and bronze medals by MM. Belot, Ehlis, Hauman-Devos, Ernhardt, and many others. The distribution of prizes will take place on the 11th inst., the day the exhibition closes. The ceremony will be presided over by the Comte de Flandre.

Electric Traction at Geelong.—At a special meeting of the committee of the Geelong and District Electric Tramway Conference, held recently for the purpose of considering the report of the sub-committee in respect to the tender of the Electric Lighting and Property Investment Company, the tender submitted was for the right to run tramways in Geelong, Newtown and Chilwell, Geelong West, and South Barwon, offering 25 per cent. of the profits after a first charge of 8 per cent. per annum had been reserved for the benefit of the shareholders, and also to give an annual subsidy, the minimum of which should be £100, to the councils. The tender was accompanied by a cheque for £250. There being a difference of opinion at the conference then held, the matter was referred to a sub-committee, who now brought up a report. After some discussion it was resolved that the tender received, subject to ratification by the respective councils, should be accepted.

Electricity and Mining.—At the meeting of the Midland Institute of Mining Engineers, held at Barnsley last week, Mr. Rhodes, the newly-elected President, delivered his inaugural address. Amongst other topics he spoke of the applications of electricity to mining, and said that as a motive power it was pushing itself to the front, and it was far from improbable that, as it became better known and appreciated, it would take the place of every other motive power in use for mining purposes, chiefly because of the ease with which power could be conveyed long distances from one station. In future the colliery and mining engineer would also have to be an electrician. He hoped the question would be dealt with in Papers to be read before the Institute at an early date. For illuminating purposes the question of a portable electric safety lamp was solved, save for the heavy first cost, and he was sanguine that before long the cost would be reduced so as to bring them within the reach of every colliery.

The Action of Electricity on the Vesicles of Condensed Water.—In the *Archives des Sciences Physiques et Naturelles* M. J. L. Soret recently described the following interesting experiment:—In a dark room a platinum cup containing water is placed on a metal support, which is connected with one pole of a Topler machine. Above this cup a metal point is placed which is connected to the other pole of the machine. A Bunsen burner boils the water in the cup, which is powerfully illuminated by the projection of a large pencil of the electric light. As long as the Topler machine is at rest the vapour vesicles ascend in the ordinary way; but as soon as the machine is at work the action of electricity on the vapour is manifested in a most striking manner. For a certain distance from the point to the surface of the water the clouds collect and whirl along the edge of the cup; under the influence of the electric light they look to a certain extent like flames. If the point is brought a little nearer the water the vapour disappears completely, although the water commences to boil briskly.

Society of Arts.—The One Hundred and Thirty-fifth Session will commence on Wednesday, the 21st November, with an opening address by the Duke of Abercorn, C.B., Chairman of the Council. Previous to Christmas there will be four ordinary meetings, in addition to the opening meeting. At the first ordinary meeting of the Society a Paper will be read by Colonel Gouraud on "The Phonograph." This will be followed by one by Mr. Henry Edmunds on "The Graphophone." At the other two meetings to be held before Christmas the Papers will be by Mr. W. H. Deering on "Explosives," and by Mr. W. J. Dibdin on "Standards of Light." Among the Papers announced for the latter part of the Session may be mentioned—"Manufacture of Sèvres Porcelain," by Mr. E. Garnier (Director of the Sèvres Manufactory); "The Forth Bridge," by Mr. Benjamin Baker; "The Channel Tunnel," by Colonel Hozier; and "Secondary Batteries," by Mr. W. H. Preece, F.R.S. The first course of Cantor Lectures will be by Captain W. de W. Abney, C.B., F.R.S., on "Light and Colour;" the other lecturers will be Mr. Alan S. Cole, Mr. W. J. Linton, Mr. Walter Crane, Mr. C. V. Boys, F.R.S., Mr. H. Graham Harris. The Juvenile Lectures, at Christmas, will be given by Prof. Henry E. Armstrong, Ph.D., F.R.S., the subject being a chemical one.

Strange Lightning Phenomena at Geneva.—During a terrible storm which burst over Geneva on the 2nd October several interesting meteorological phenomena were observed, and amongst others a globular discharge which took place at Lancy, near Geneva. The house struck was in an isolated position, and closely surrounded by high trees, the branches of one of the highest almost touching the roof. The building was provided with two lightning-conductors. M. R—— was sitting with his clerk in a room on the first floor, the door, which led into a passage, being wide open. Suddenly a ball of fire about 3 centimetres diameter appeared in the doorway at a height of nearly 1 metre from the floor, and burst with a noise like that of a pistol-shot. Nearly simultaneously M. R—— saw through the window a shower of "golden spangles." The lightning-guards of the telephones in the room and at the vaccination institution 500 metres off, which were in direct communication, were both slightly burnt. The bell and telephone wires were not injured inside the house, but the outside wires of both were damaged. For a distance of about 20 metres the telephone wires, at the point where they joined the village telegraph posts, were melted, and the insulators were blackened. A gutta-percha covered telegraph wire close by was destroyed for the length of a metre. Neither the roof of the house nor the surrounding trees were touched.

Berlin.—The work done by the Edison Company in this town is so good, says *Industries*, that the public and the municipal authorities have perfect confidence in their ability to extend their central station work still further, and a concession has been given to this company for the establishment of two new stations—one in the centre of the town and the other in the south-east quarter, where most of the engineering works and other factories are situated. Both stations must be ready within two years, and each must be able to supply current for 6,000 glow lamps burning simultaneously. The station in the centre of the town will eventually be increased to a capacity of 24,000 lamps, and the other station will be increased to 12,000 lamps, the annual increase to be not less than 6,000 and 3,000 lamps respectively. All the cables required in connection with these stations must be in position by the end of 1892, and the supply of current within both districts will be compulsory, provided the customer is willing to take the light for at least one year. The network of cables to be laid down in connection with these stations is very complete, and practically comprises all the streets of the respective districts, some small and unimportant side streets alone excepted. In view of this extension of their business, the Edison Company propose to increase their share capital at present by £150,000, and later on by £300,000. The electric light installation in the Monopol Hotel of this town, which comprises 1,000 lamps, will shortly be in action. The work has been executed by the Berliner Maschinenbau-Actiengesellschaft, under the superintendence of Herr Beringer. The current is supplied by two 80 horse-power dynamos, each direct coupled to a twin engine. The dynamos are of the eight-pole disc type, and are compound wound. Steam is suppliedby two Babcock and Wilcox boilers, having collectively a heating surface of 2,400 square feet.

Hastings.—At the last meeting of the Hastings Town Council the Public Lighting Committee recommended that the existing contract with the Electric Light Company, for the lighting of the front, from the Queen's Hotel to Warrior-square, by means of fifteen 2,000 nominal candle-power arc lamps for the sum of £450 per annum, which expires on the 26th of November, be renewed for another year, subject to the company substituting lamps of the new pattern where not already done.—Councillor Jenner said the Electric Light Company had consented to erect new lamps, which had proved a great advantage, and did not throw shadows across the road or pavement. The electric light had taken such a hold on the people that it would be difficult for them to shake it off. It was a very beautiful light, he admitted, but also a very expensive one.—Councillor Revill said he had been a consistent supporter of the electric light from the commencement. He believed the light had been the means of attracting people to the town. He hoped that in the near future the light would be cheaper. He had nothing to say against the gas company, but he contended there was plenty of work to do, not only for the gas company but the electric company also.—Councillor Stanger complained of the expense of the electric light.—Councillor Duke said the difference between lighting with the Whitehall lamps and the present system had been calculated, and it was found there was a difference of only £150 against electricity. Visitors and others would agree that the £150 was well laid out.—Councillor Hutchings opposed the adoption of the report. He thought the Whitehall lamps were sufficient for the purpose, and if they could save £150, why should they not? In deference to his pledge to economy he felt bound to oppose the electric light when they could obtain efficient lighting for £150 less.—Alderman Bradnam contended that the electric light was a benefit to the town at large; but if at the end of 12 months they preferred to relinquish it they had the power.—The motion was carried.

The Town Council and Electric Lighting in Birmingham.—The following is the most important portion of the report which will be submitted to the Birmingham Town Council by the Committee to which the electric lighting question was referred: "On the 23rd October your committee had an interview with Messrs. Chamberlain and Hookham, accompanied by their solicitor, Mr. Pinsent, and pointed out various objections to the draft provisional order, when, after considerable discussion, the promoters decided to withdraw the order in the form originally presented, and to substitute an amended order, with the view of meeting certain of the objections raised by your committee. On the 2nd November the town clerk received an amended form of order, which more closely followed the model form approved of by the Board of Trade, and known as 'The Chelsea Order, 1886.' By this order it is proposed, within three years from the date of the same, to lay down distributing mains in a considerable area in the centre of the town, and to include the whole borough within the provisions of the order for the purposes of future extension. It is quite obvious that your committee will require considerably more time before they can present any definite recommendation upon this subject, and it becomes a matter worthy of consideration whether the better plan will not be to decline to consent to an order at present, with a view to the whole question of electric lighting under the provisions of the Act of 1888 being carefully inquired into on behalf of the Corporation. Another reason for delay is that your committee have now before them several applications from other persons for permission to place overhead wires across the streets for the transmission of electricity; and it appears to your committee that the subject of electrical light and power distribution demands more time and attention than it has been possible to give it up to the present date. The question has been again raised as to the propriety of the Corporation themselves obtaining an Act or provisional order for the supply of electricity within the borough, and it becomes necessary to ask for further time for consideration before arriving at any conclusion upon so important a subject. Your committee, therefore, recommend that the consideration of the Birmingham Electric Light and Power Order be deferred for the present."

NOTES ON ELECTRO-MAGNETIC INDUCTION.

BY DR. J. A. FLEMING, M.A.

(Continued from page 815, Vol. XXI.)

Henry was followed in his researches on Leyden jar discharges and the currents induced thereby in adjacent circuits by Abria, Marianini, Reiss, and Matteucci. Matteucci endeavoured to determine the direction of the induced discharges by employing a process founded upon the experiment of the pierced card, in which the hole made by the spark on a piece of paper or a card is always nearer to the negative electrode. By means of this process, combined with the employment of the galvanometer, Matteucci considered that the inductive discharges are determined by the following law:—If the inducing and induced circuit are both closed, the induced discharge is in the *opposite* direction to the inducing discharge. If, however, the induced circuit is interrupted at any point so that there is a spark, the induced discharge is in the *same* direction as the inducing. Abandoning these methods above described, M. Verdet* employed another, which depends upon the *polarisation of electrodes* in dilute sulphuric acid.

From more recent knowledge we may state the facts with regard to the action of alternate currents upon a dilute sulphuric acid voltameter as follows†:—

If a current of electricity consisting of alternate short fluxes of current of opposite sign is passed through a voltameter having platinum electrodes, and if these electrodes are large, there is no visible decomposition, but if the electrodes be reduced in size below a certain limit visible decomposition begins. For every current there is a certain size of electrode, below which gas is not visibly evolved, and for every given size of electrode there is a current below which gas is not apparently liberated. When the conditions are suitable for the liberation of gas the gases collected at both electrodes have the same composition. If the quantities of electricity passing in each alternate and oppositely directed flux are equal, then the electrodes are not sensibly polarised. If, however, the quantities are not equal, then there is, on the whole, a greater flow of current in one direction than the other, and the electrodes exhibit the state known as polarisation, and yield a reverse current when connected with the galvanometer. Verdet, in his experiments, made use of flat spirals, the wires of which were insulated from each other with great care by silk and a layer of gum-lac varnish. The primary spiral was made of copper wire $\frac{3}{4}$ths of an inch in diameter and 92 feet in length, forming 24 spirals. The secondary circuit consisted of three spirals of wire $\frac{1}{10}$th of an inch in diameter and 157 feet in length, making 95 turns. The inducing discharge was supplied from a Leyden jar battery of 9 large jars. The induced discharge was sent through a voltameter having small platinum electrodes, and which could be connected with a delicate galvanometer for detecting polarisation of the electrodes immediately after the discharge. M. Verdet's experiments led him to recognise that when the induced circuit is continuous, and not interrupted anywhere except by the insertion of the voltameter, no traces of polarisation are obtained except by very powerful discharges. This indicates that the induced discharge consists of a double current of two oppositely directed and equal quantities of electricity. In the case of very powerful discharges there was a slight galvanometric deflection, indicating a preponderating secondary discharge in the *same* direction as the primary. If the induced or secondary circuit is interrupted at one point, so that the discharge has to pass as a spark at that place, then very perceptible polarisation of the electrodes presents itself, and the direction of this is such as to indicate a predominant induced current passing in the *same* direction as the primary.

To sum up. It follows from all the numerous researches on induced discharges that this is a very complex phenomenon, and is influenced by a large number of conditional circumstances, and also by the very mode employed for determining it. It may be, however, taken as proved that an induced discharge, produced either as a secondary discharge by a transitory primary, such as the discharge from a Leyden jar, or a tertiary current produced by induction by a secondary current of very brief duration, is in its simplest form a wave of electric current, consisting of two short fluxes or currents in opposite directions, and succeeding each other immediately. This Poggendorff* holds to be shown by the action of such tertiary or higher order currents on a galvanometer. If these currents are led through a galvanometer of which the arrangement is such that the magnetic axis of the needle is accurately at right angles to the direction of the magnetic axis of the coil, then no deflection of the needle is observed, or at most a very slight one. If, however, the needle makes an angle with the plane of the coils, then these induction currents cause a deviation of the needle. This effect (*der doppelsinnigen Ablenkung*) arises from the fact that the magnetism of the needle is not rigid, and that the alternate twisting couples to which the needle is subjected are not equal, by reason of the fact that one of the halves of the complete induced current—say the direct half—increases the magnetic moment of the needle, and hence increases slightly the deflecting couple in the direction tending to increase the deviation of the needle; the other half—say the inverse part of the induced current—tends to reduce the moment of the needle, and hence to subject it to a smaller reverse couple. Hence it follows that, if discharges of equal quantity and opposite sign succeed each other through a galvanometer when the needle is accurately in the plane of the coils, little or no deviation is observed; but if the coils are turned so that the needle makes an angle with them, then these alternate currents will affect the needle and increase the angle of deflection.

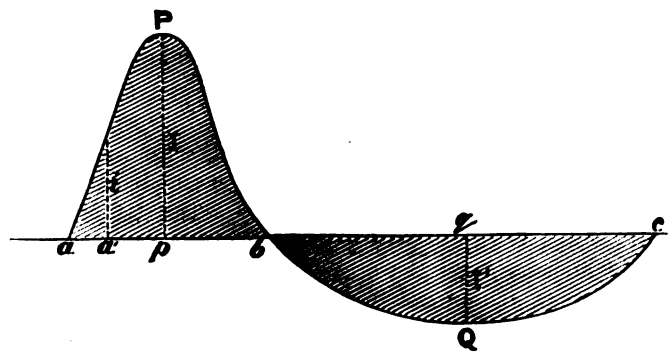

FIG. 9.

This behaviour towards a galvanometer, and the action on a voltameter of liberating mixed gases of equal composition at each pole prove that each induced current of the third and higher order consists of two oppositely directed discharges, produced by the operation of two successive electromotive impulses of opposite sign and very brief duration acting upon the circuit. The quantities of these discharges are equal; but the durations are different, and hence the maximum value of the current strength during the opposite discharges may be very different. This may be illustrated graphically thus:—

Let the curve a P b Q c (Fig. 9) be a current curve representing two waves of current of opposite sign succeeding each other. Let the horizontal line $a c$ be a time line, and vertical ordinates represent instantaneous current strengths. Then the areas (shaded) will represent the *quantity* in each discharge. Let these shaded areas be equal, then the diagram represents two discharges of equal quantity succeeding each other in opposite directions, but having very different maximum current strengths I and I'. The duration of the first discharge is represented by $a b$, and that of the second by $b c$. This diagram represents, then, what we find in the simplest case of tertiary current. If the instantaneous value of the current at any time is called i, then the whole quantity of the discharge will be represented by the shaded area and by the integral $\int i\,dt$ between proper limits.

We may classify the effects of induced discharges or currents in the following way :—

(1) Those effects dependent upon $\int i\,dt$, or upon the whole quantity of the discharge. These are the *galvanometric* and the *electro-chemical* effects. If a discharge is passed through a galvanometer, the duration of which is very small compared with the time of free oscillation of the needle, the galvanometer needle experiences a "throw" such that the sine of half the angle of deflection is proportional to the whole quantity of the discharge. Also in a voltameter, by Faraday's law, the whole quantity of the electrolyte broken up is proportional to the quantity of electricity which has pass through it.

(2) Those effects dependent upon $\int i^2\,dt$, or upon the average of the square of the strength of the current at every instant during the discharge. These are the *heating* and the *electro-dynamic* effects. By Joule's law at every instant the rate of dissipation of energy is proportional to the square of the current strength, and hence the whole heat generated by the discharge is proportional to the integral above. Similarly, if the discharge passes through a circuit, part of which is movable and can react upon a fixed part, so that attraction or repulsion may take place between them, the force is dependent at any instant on the square of the current strength, and hence the whole effect or average force upon the same integral.

(3) We have, lastly, effects dependent chiefly upon the maximum ordinate I, or upon the rate of change of the current—that is, upon the steepness of the slope of the current curve. These are the *physiological*, *telephonic*, *luminous*, and *magnetic*.

The physiological effect of a discharge in giving a shock appears to depend in great part upon the suddenness with which the maximum current strength is reached. Of two discharges which reached equal maxima, that which arrived at it in the shortest time would be the most effective in producing shocks. The value of the maximum current strength is also important. Two induced currents of equal quantity but different duration cause a greater shock in proportion to their lesser duration. The telephone in this respect resembles the animal body. It is affected more by the rate of change of the current strength than by the absolute current strength at any instant.

The *magnetic* effect depends, as has been shown by Lord Rayleigh,* upon the maximum current strength during the discharge, or upon the initial current strength, in those cases in which the current dies gradually away. In the two Papers referred to below it is shown by direct experiment that, since the time required for the permanent magnetisation of steel is small compared with the duration of induced currents generally, the amount of acquired magnetism depends essentially on the initial or maximum current strength during a transitory current, without regard to the time for which it lasts. It is, then, not difficult to understand that the effort to settle by experiment with a magnetising coil the direction of induced discharges may lead to very conflicting results, and, in any case, it is hardly competent to do more than indicate the direction in which the maximum current flow takes place during the discharge.

The *spark* effects are also included in this category. The air or other dielectric is broken down when the difference of potentials between the two discharging points reaches a certain magnitude, and in the case of a varying electric pressure the question whether a spark will pass or not is evidently determined by the maximum magnitude of that quantity.†

It is evident from the above considerations that the complete analysis of the effects and phenomena of induced currents of the higher orders, and of those of secondary currents due to discharges from condensers, requires a knowledge of the *form* of the current curve in each case.

LIGHTNING CONDUCTORS.—II.

BY DR. OLIVER LODGE.

Record of Experiments on the Alternative Path.

As explained last week, I proceed to record the series of experiments I have made on the E.M.F. needed to drive a given discharge through a conductor. These experiments are mixed up in my note-book with a number of others made with slightly different objects, but it will be clearer if I pick out all those of one kind first, and attend to the others afterwards.

I begin with some early experiments—the first tried by me—when the arrangements for measuring spark length were comparatively imperfect (a graduated wedge was inserted between the knobs of the discharger), and when the essential conditions were less understood. They are not so immediately available for testing theory, but there are some instructive points about them nevertheless.

Early Experiments. February, 1888.

7. A copper wire, about No. 22 B.W.G., and an iron wire, about No. 20, were stretched round the lecture theatre (a length of some 35 yards), being suspended by silk threads from four vertical posts a good way off every wall. A large condenser, consisting of 16 pairs of 11in. square tinfoils separated by double thicknesses of window glass each about $\frac{1}{10}$in. thick, the whole soaked and embedded in a mass of paraffin and enclosed in a teak box, was used. [The capacity of this condenser was subsequently determined as ·028 microfarad.]

The condenser was charged through the long wire, and a choice was offered the discharge, so that it might go either round the wire or leap an air-gap, as it chose.

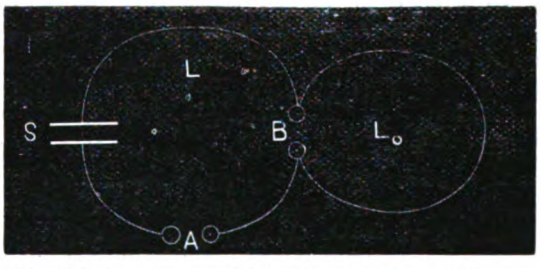

FIG. 2.—This figure is repeated for the convenience of the reader.

A are the ordinary terminal knobs of the machine where the spark occurs; B is the discharge interval alternative to the wire or to other resistance. The spark length B was adjusted so that it was an off chance whether the discharge chose it or the wire. It was noticed that when the discharge chose B the A spark was strong, but when the discharge chose the wire the A spark was weak. The difference appeared to be only in the noise or suddenness of the spark, for when a Riess's electro-thermometer was inserted in the circuit it indicated about the same in either case. A number of observations were made with this energy-measuring arrangement, but I appear to have no record of them.

The following are the spark length readings :—

Critical B Spark length.	*Choice open being,*
·60 inch	... Iron wire round room.
·61 ,,	... Copper ditto.
·64 ,,	... Both wires in series (currents in same sense).
·60 ,,	... ditto. (currents in opposite sense).
·97 ,,	... A 6-inch capillary glass tube full of tap water.
·74 ,,	... The same tube full of dilute acid.
·02 ,,	... A short copper wire 2ft. long.
·075 ,,	... Very thick iron rod a yard long.
·075 ,,	... Very thick brass rod a yard long.
·11 ,,	... 18 inches of thin brass wire.
·11 ,,	... The same taken once through a large ring of iron wire.
·16 ,,	... Ditto.

This was the first experiment that distinctly suggested that the ordinary magnetic properties of iron were suspended under these circumstances. The iron ring was in the position of the iron core of a transformer, and yet it exerted no appreciable

Digitized by Google

effect on the impedance of the wire round it.* The experiment was made because the previous experiments had indicated how equal iron and copper seemed, showing none of the expected great difference between them.

The readings in these experiments are not to be supposed at all accurate, and the second place of decimals means very little. No doubt the actual *readings* are taken correctly enough, but we had as yet by no means hit on the best procedure for determining the critical B spark with any nicety, and in this first set of experiments the length of the A spark is not recorded.

8. A set of observations was now taken with the object of seeing what effect the length of the A spark had upon B under these circumstances.

Experiments on the Connection between Lengths of A and B Sparks.

(The alternative path being the iron wire round the room all the time.)

A Spark length. inch.	Critical B Spark length. inch.	$\frac{B}{A}$
·12	·095	·8
·225	·22	·98
·28	·30	1·07
·31	·35	1·13
·36	·405	1·10
·40	·48	1·20
·46	·575	1·25
·537	·648	1·21
·578	·726	1·26
·587	·726	1·24
·587	·744	1·27

The ratio of B to A thus increases with the energy of the discharge, but seems to approach a limit.

9. Now arrange a gallon Leyden jar (of capacity, as subsequently determined, 55 metres electrostatic units, or ·006 microfarad) as a lateral appendage to the B terminals, in the same way as the condenser of an induction coil is a lateral appendage to the contact breaker; the idea being that it would reduce the liability to spark across B, and help the discharge to choose the wire path.

Alternative path.	A readings. inch.	Critical B readings. inch.	$\frac{B}{A}$
Iron wire round room	·533	·498	·92
" "	·428	·397	·93
" "	·28	·267	·95
" "	·145	·123	·85
Copper wire round room	·145	·123	·85

10. The jar was now removed and the experiments continued.

Wire round room	·295	·339	1·15
Capillary tube containing acid	·240, ·255, ·266	·339	1·41, 1·37, 1·27
Acid tube and wire in parallel	·296	·339	1·15
Same with wire cut in middle, and ends separated a few inches†	·286	·339	1·18
Wire and acid tube in series; acid tube in middle of wire, filling up gap	·282	·339	1·2
Ditto with gap mended; acid tube at one end of wire	·274	·339	1·2
Ditto acid tube at other end	·266	·339	1·27
Acid tube only, the wire being included in the rest of the circuit	·266	·339	1·27

When the acid tube was the alternative path, and the B knobs so far apart that the discharge was obliged to choose it, the A spark was very weak, being reduced to a quiet spit, which could be analysed by a slowly rotating mirror into several detached sparks.

11. The resistance of the capillary acid tube so frequently mentioned was afterwards estimated as follows:

The tube full of mercury	·437 ohm.
The tube full of zinc sulphate solution, of strength $\frac{ZnSO_4, 5H_2O}{20}$ in 100 cc, with zinc electrodes. No difference on reversing battery	177,000 ohms.
The tube full of extremely dilute acid as generally used	from $\frac{1}{4}$ to $\frac{1}{2}$ a megohm.

* This led on to a series of experiments on the effect of iron cores, and on the magnetisation of steel and iron by a discharge.

† The brushes and vigorous disturbances subsequently seen at this gap led on to a series of experiments on "the recoil kick."

Experiments with a Smaller Condenser.

12. Instead of the large condenser, I now tried either a pint or a gallon Leyden jar (capacity ·0016 or ·0061 microfarad) and got much the same results. The jar often overflowed its edge and self-discharged, but a spark still occurred at B when this happened, though not at A.* Hence, an overflow path was provided, at C (Fig. 7); and sparks at B and C could be got, but not at A; or at A and B and not at C; or at C only.

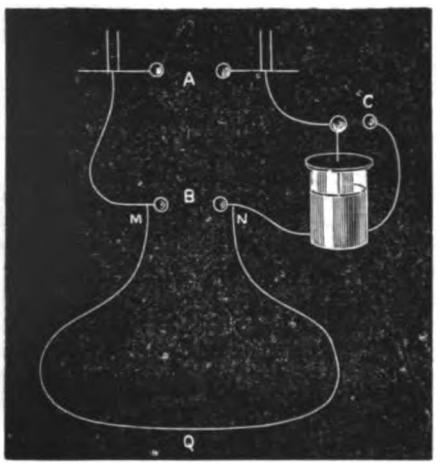

Fig. 7.

It was found that connecting the knob of the jar to earth, the jar itself being insulated, increased the strength of the B sparks very much, and made them easier to get. Evidently the wire was acting as one coat of a condenser, the wall being the other coat.

13. Putting acid resistance into the circuit at M or at N weakens but does not stop the B sparks, and it has the same effect at M as at N. But inserting resistance at Q does not weaken the B spark perceptibly; neither does cutting the wire there, only of course, in order to permit the charging of the jar, the B gap has to be bridged by some very imperfect conductor, this shunt high resistance having no appreciable effect upon the B spark.

14. The jar was now discarded, and the wire alone used, as in Fig. 8. The sparks occurred at B perfectly well,† and were much the same whether the wire was cut at Q or not.

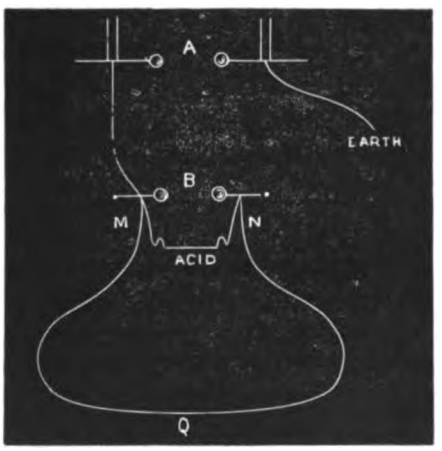

Fig. 8.

After a great number of experiments in various other directions, "overflow," "recoil kick," "liability to be struck," "side flash," "gauze house," "bye path," &c., some more experiments on alternative path were done, and to these we now proceed.

Further Experiments with Various Long Leads, March, 1888.

15. I had now arranged round the theatre a couple of very stout wires, almost rods, supported by silk ribbon, each about

* This led to a series of experiments on "overflow."

† This led to a series of experiments on the "surging circuit."

Digitized by Google

27 metres long, one of No. 1 iron, the other of No. 1 copper; besides these there were a couple of leads of ordinary thickness, each about 30 metres long, viz., No. 18 iron, No. 19 copper, and one lead of fine iron wire, No. 27, also 30 metres in length.

The resistance of these leads measured in the ordinary way, Carey Foster's method being used for the short ones, was

Resistance of No. 1 copper	·0254	ohm.
,, ,, 1 iron	·0881	,,
,, ,, 19 copper	2·72	,,
,, ,, 18 iron	3·55	,,
,, ,, 27 ,,	33·3	,,

The copper is evidently of shocking bad electrical quality, but so is most of all of what one buys at an ordinary metal merchant's. I must say, however, that the Birmingham wire gauge nomenclature is never intended to be anything more than roughly descriptive of the wire. When one wants to know its diameter really, of course one measures it.

Sectional radius of the No. 1 copper lead	·37	centimetre.
,, ,, ,, 1 iron	·355	,,
,, ,, ,, 19 copper	·0425	,,
,, ,, ,, 18 iron	·060	,,
,, ,, ,, 27 ,,	·0175	,,

Each of the two thick leads formed a rough rectangle about 840 centimetres by 515 centimetres, the entire length of each wire being 2,710 centimetres. The three thinner leads formed rough rectangles of 840 by 675 centimetres, and the length of each of these was 3,030 centimetres.

These dimensions are necessary to be known, in order that we may hereafter calculate their coefficient of self-induction.

The static electric capacity of the leads was determined roughly by charging them with 144 small cells, discharging through a ballistic, and comparing the kick with that obtained from a small jar of known capacity treated in the same way.

The results (quite rough) are

Electrostatic capacity of either thick lead	5	metres.
,, ,, either medium lead	3½	,,
,, ,, thinnest lead	3	,,

16. For the alternative path experiment with these leads, arrangement Fig. 5 was adopted, two gallon jars being used; the A knobs being those of the machine, while the B knobs belonged to a universal discharger. The only divergence from the figure was that the ends of the alternative path were connected direct to the outer coats of the jars instead of quite directly to the B knobs. The length of the A spark was kept at 1in., the B knobs were adjusted till their spark just began to go.

Alternative Path.	*Length of B Spark.*
No. 1 copper round room	1·43 inch.
No. 27 iron ,,	1·03 ,,
No. 1 iron ,,	1·08 ,,
No. 19 copper ,,	1·34 ,,
No. 18 iron ,,	1·08 ,,

At the rooms of the Society of Arts these same, or very similar, leads were rigged up, and the experiment repeated, with much the same result. But instead of going round the room the leads were only taken to the end of the room and back, with about 3 yards interval between going and return wire, and the circuits were not arranged one over the other, but all in the same horizontal plane, side by side.

Experiments to Determine the Effect of Self Induction.

17. To help study how much of the effect was really due to self induction I procured a piece of thick stranded double wire cable, each wire being thickly covered in gutta percha, and then the two enclosed in a gutta percha sheath. The ends could be joined in various ways, so as to put the wires in series with the currents going in the same direction, *i.e.*, with a maximum of self induction, or in series with them going opposite ways, so as to have a minimum of self induction ("anti-inductively," so to speak), or in parallel, or in any other way.

The length of the bit of cable was 770 centimetres, and it was arranged to form a rude circle. The ordinary resistances of its wires were ·0608 and ·0586 ohm respectively.

Keeping exactly the same arrangement as before, with the A spark still 1in., the experiments were as follows:—

Alternative Path.	*Length of B Spark.*
The two gutta-percha-covered wires in series, so as to enclose max. area	1·77
The two wires in series, currents enclosing min. area	·91
The two wires in parallel	·91
One wire alone	·91
One wire alone, the other having its ends joined, so as to form a closed secondary	·79

18. A number of experiments were now made with this bit of cable, and with a great thick No. 1 copper open spiral, by inserting large masses of iron, bundles of iron wire, iron bars and rings, into their contour, to see what difference the iron made. So far as one could tell it never made any. To take definite readings, therefore, I got my assistant to make an induction spiral of tinfoil, consisting of a strip of tinfoil 3 inches wide and 21 feet long, wrapped round a glass tube with sufficient insulation between the turns. Also an anti-induction tinfoil zigzag with the same length of tinfoil.

The resistances of these were ·614 ohm for the spiral and ·708 ohm for the zigzag.

The length of the spark A being ·73 inch, the following are the readings taken:—

Alternative Path.	*B Spark.*
Tinfoil zigzag joined up to outer coats of jars by two leads, each a couple of feet of No. 12 copper wire	·23 inch.
Tinfoil spiral ditto ditto	·64 ,,
Spiral with iron wire bundle inserted in its tube	·64 ,,
Leads only (the two No. 12 wires)	·21 ,,
No path at all	1·11 ,,
Zigzag connected direct to jar, without leads	·06 ,,
Spiral ditto ditto	·64 ,,
Spiral with iron bundle inside	·64 ,,

Calculation of Self Induction of Long Leads.

19. The long leads round the room really enclose rude rectangles; but inasmuch as I do not know how to calculate the self-induction for a nearly square rectangle, and inasmuch as bending them out into a circle *of the same perimeter* would certainly not have affected their self-induction much, I reckon it by the formula (8) given last time, assuming that the depth to which the currents penetrate into the substance of the conductor is certainly small.

Using the dimension of these leads as previously given, one thus reckons in electromagnetic units,

Self induction of either No. 1 lead	390 metres.
,, ,, ,, 18 ,,	550 ,,
,, ,, ,, 19 ,,	570 ,,
,, ,, ,, 27 ,,	630 ,,

All this time it had not struck me that it was important to specially know the particulars of the part of the circuit containing the jars, and they were accordingly connected up to the machine by wires in a very ordinary manner; but as far as I can estimate the self-induction of this part of the circuit now I should say it was between 40 and 60 metres usually.

(To be continued.)

Development of Telephone Communication in Nottingham.

On Monday last the National Telephone Company opened an extension of their system at Nottingham. Hitherto the towns in telephonic communication with the centre of the lace trade have been Long Eaton, Ilkeston and Loughborough; but Derby and Birmingham have now been added, a trunk wire running through Long Eaton, Derby, Burton-on-Trent, and Lichfield to Birmingham having been opened. A trunk wire will be laid on to Coventry, from which place a connection will be made with the South of England Company's wires, and a further new wire to Sheffield will open up not only Yorkshire but the extensive district of the Lancashire and Cheshire Telephone Company.

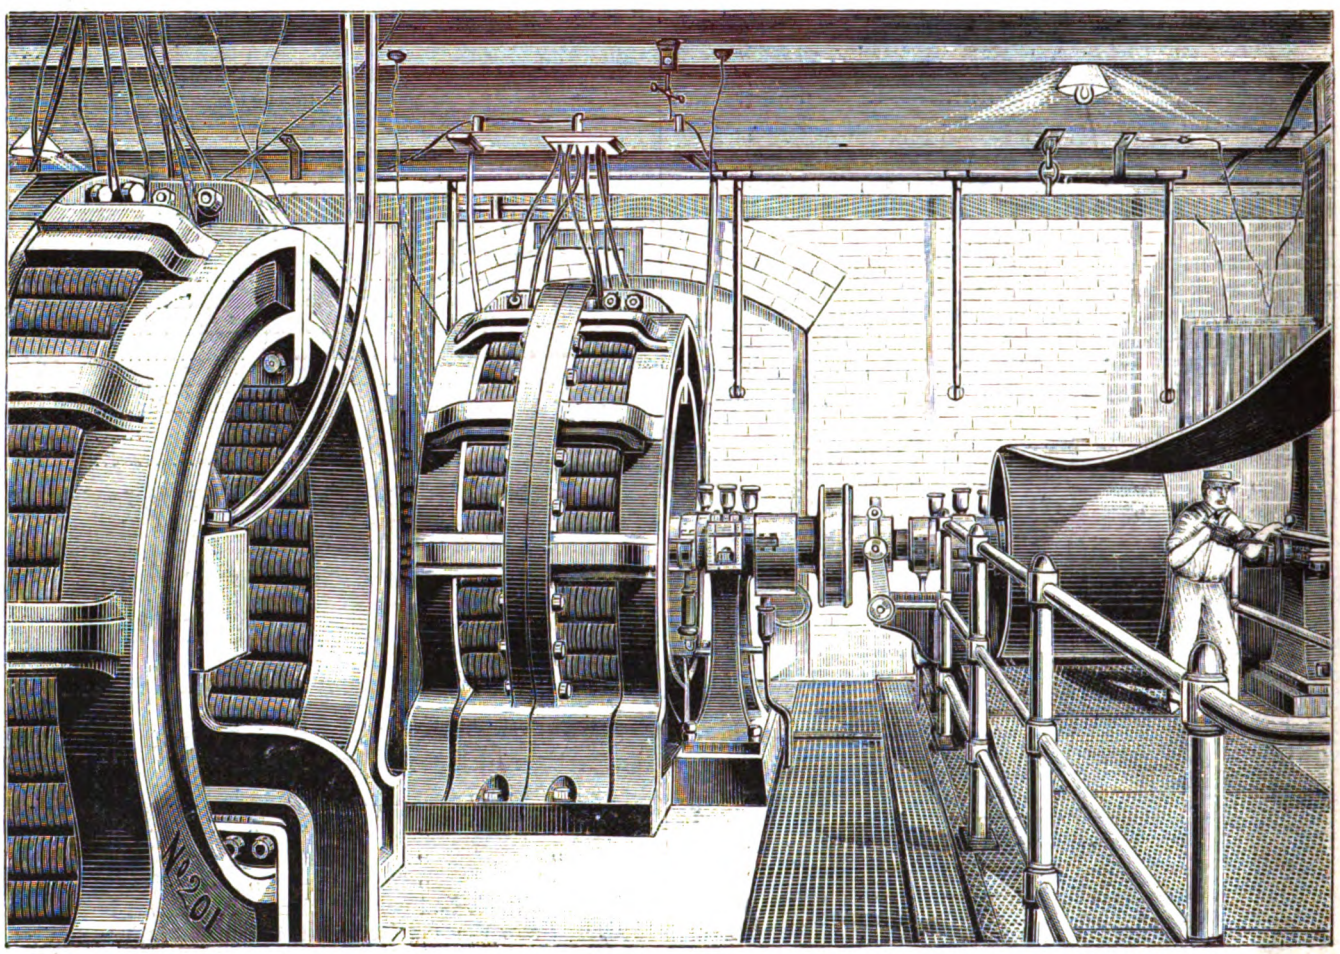
THE GROSVENOR GALLERY CENTRAL LIGHTING STATION OF THE LONDON ELECTRIC SUPPLY CORPORATION.

On Wednesday evening last, at the invitation of the directors of the London Electric Supply Corporation, the representatives of the technical press visited the Grosvenor Gallery, and inspected the Central Lighting Station. Our readers will be already aware that for more reasons than one this station will possess a unique interest in the history of electrical engineering. It was at the Grosvenor Gallery that the transformer system may be said to have had its birth. The installation has been regarded from the first by its promoters as experimental in character, and it is here that the problems have been worked out whose successful solution has imparted that remarkable degree of confidence which is now being displayed in the far vaster undertaking at Deptford. Considered merely as an extended trial of the overhead system of distributing electric lighting currents, the success attained is of the highest importance. It is, however, on account of the experimental character of their operations that the directors have hitherto refrained—and as we have all along been of opinion have wisely refrained—from sanctioning the publication of the details of a technical character. But the time having now arrived when the experimental stage of the Ferranti system is considered to have been closed—save, of course, in so far as the Deptford scheme involves new and important problems on account of its extreme magnitude—we take the earliest opportunity of furnishing our readers with an account of the Grosvenor Gallery installation. We shall confine ourselves at present to a straightforward description of the main features, reserving some of the details for more complete illustration at a later date.



THE 10,000-LIGHT FERRANTI DYNAMO AT THE GROSVENOR GALLERY.

The total number of lamps at present wired in connection with the Grosvenor Gallery Station is equivalent to about 35,000 of 10 candle-power; but it has hitherto been found that 20,000 represents the maximum number in use at one time, and this number is but rarely exceeded. To supply current for these lights, two Ferranti machines are provided, each of which was designed for 10,000 10 candle-power lamps, but one machine alone has proved itself capable of taking a load of no less than 19,500 lamps without injury. These machines stand 9ft. 6in. in height, with a floor space 9ft. by 11ft. The armature is not built up in the way usually associated with the name of Ferranti, but is composed of separate bobbins, after the Siemens type. The coils are wound on laminated cores of gunmetal and German silver, and are composed of copper tape ½in. in width by ·06in. in thickness. The tape is slightly corrugated in order to prevent its slipping on the crown of the core, which is also corrugated to receive it. The insulation is wound on with the tape, and consists of hard vulcanised fibre of ½mm. thickness. One end of the bobbin is soldered to the core, which is insulated from the frame by blocks of ebonite held in cast-iron clamps. In the Deptford machines we understand that an improved method will be adopted. There are forty coils, each consisting of 25 turns, connected 20 in series and two in parallel, so as to keep the points of maximum difference of potential at the opposite extremities of a diameter. The diameter of the armature is 8ft. 6in., and its resistance when hot 1·1 ohm, which at 2,400 volts gives a loss of only 7,000 watts, or 1·36 per cent. on the maximum output. The speed is 260 revolutions per minute, which is equal to a peripheral velocity of 6,942ft. per minute. The field-magnets are eighty in number, and are set very close together, forty on either side. The coils are connected in eight parallels, and have a resulting resistance of one ohm nearly. The field-magnets weigh 17 tons, the base plate

Digitized by Google

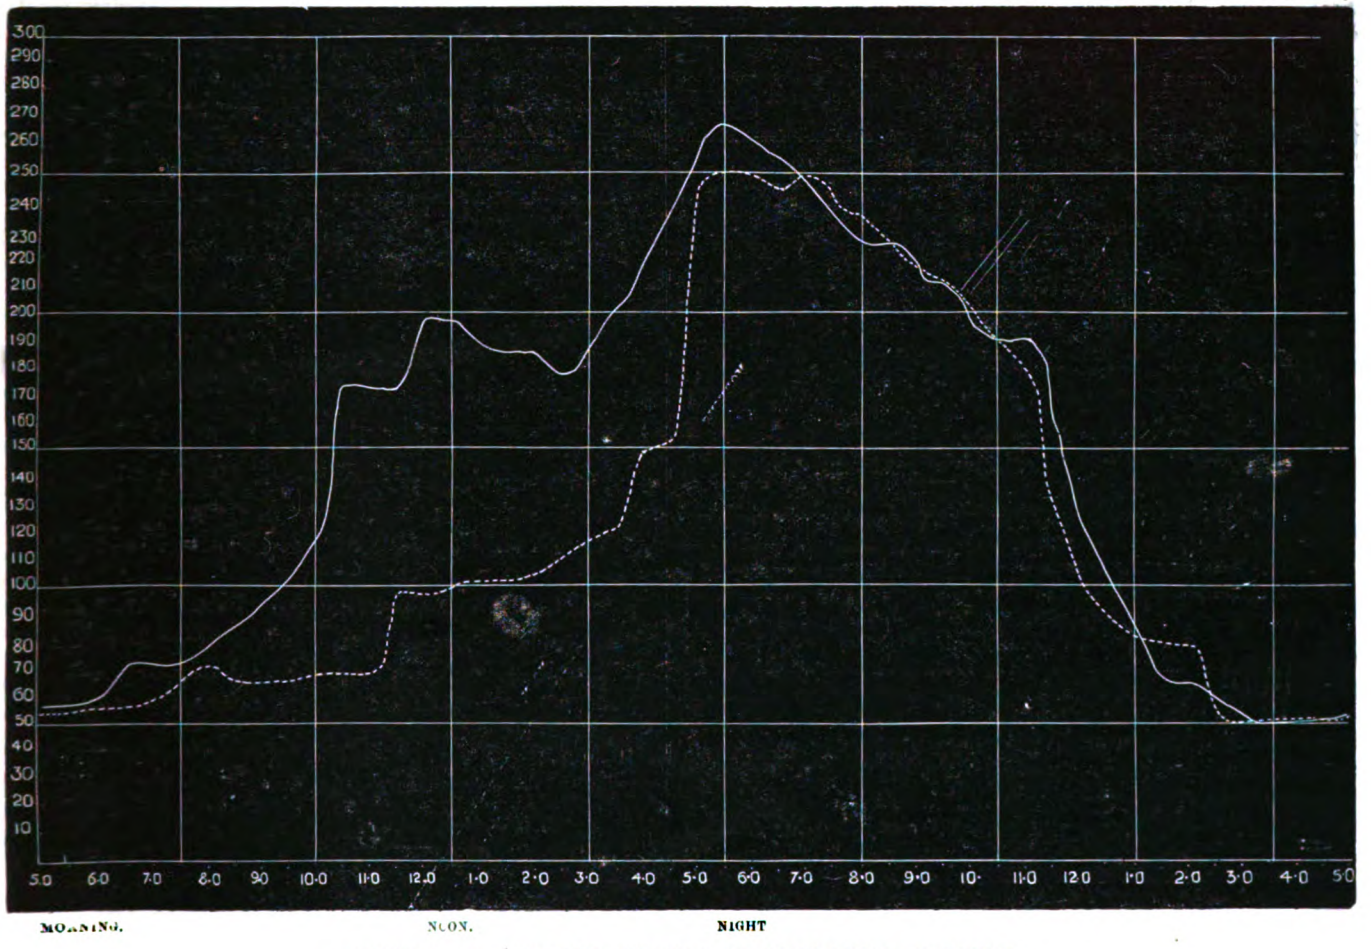
13 tons, the pulley (diameter 5ft.) weighs 2 tons, and the armature one and a-half ton.

The exciters are shunt-wound Siemens machines, giving 100 volts and 108 amperes; they are coupled direct to the shafts of the Ferrantis. The latest addition to the plant is a twelve-unit Kapp machine, also shunt wound, which is at present used chiefly for lighting the engine room, but is also intended as a stand-by for the exciting current in case of need. Switches are arranged for this purpose. There is a constant oil service for each of these machines; the tank holds 300 gallons, and the circulation is effected by two Worthington pumps. Castor oil is used, and the used oil is returned through two strainers.

The engines are four in number, two being Marshall single-cylinder, horizontal engines, of 35 horse-power nominal; one a coupled engine, similar to the above, capable of developing 500 horse-power actual; and one a Corliss, by Hick, Hargreaves and Co., of 750 horse-power. The Marshall engines run at 80 revolutions, and drive on to a single countershaft with clutches so arranged that very nearly any desired combination of engines and dynamos may be effected. The smaller engines have 19in. cylinders with 3ft. stroke, and fly-wheel 13ft. in diameter. The coupled engine has 17in. cylinders, with 3ft. stroke and fly-wheel 12ft. in diameter. The Corliss engine has 33in. cylinders, with a 4ft. stroke, and a fly-wheel 18ft. in diameter. One of the large machines is driven direct from the fly-wheel of the Corliss engine by rope gearing. The other machine is connected by means of a claw clutch with the countershaft driven by the Marshall engines, as already described. The clutch has been specially designed for this purpose by Mr. Ferranti, and it is so effective that when the machine is loaded to 400 horse-power a change can be made without any perceptible effect upon the lamps.

The regulation of the dynamos is effected solely by the governing of the engines. Ordinary centrifugal governors of Hartnell's type are used, and the speed is regulated in accordance with the indications of a Cardew voltmeter by means of a weight sliding on a lever arm. Nothing is more striking in the whole installation than the simplicity and effectiveness of the governing arrangement. The Cardew voltmeter is used only as a "voltascope"—that is to say, it is connected with a small transformer, and its indications are on an arbitrary scale.

The steam generating plant consists of a battery of four Babcock and Wilcox boilers, each of 150 horse-power, worked at a pressure of 130lb., and blowing off at 135lb. When the station is in full swing all four boilers are required, so that there is practically no reserve. The fires are only drawn on Sunday. The water-tank contains a three-days' supply, and there is storage capacity for thirty-six tons of coal. The average daily consumption amounts to 23 tons. The boilers are placed in an excavation, this room being connected with the engine room by a tunnel 40ft. or 50ft. in length, which also serves as a ventilating shaft. The offices and stores are above the boilers, with the water tank on the top story. The ventilation is effected by means of a 72in. Blackman air propeller, running at 200 revolutions, which is found to do its work with remarkable efficiency.



CURVES OF CURRENT OUTPUT AT GROSVENOR GALLERY.

The dotted curve was taken on Monday, October 29th, and the upper curve on Thursday, 1st inst., when a dense fog occurred.

Coming now to the circuit arrangements and the distributing plant—the current passes direct from the machines to a pair of Sir William Thomson's ampere-balances, capable of measuring 250 amperes. The maximum current taken off each machine is about 210 amperes. The machines are run independently—that is to say, they are not electrically coupled in parallel. The external circuits are five in number, and the main switches are specially designed by Mr. Ferranti for breaking on the high-tension of 2,400 volts. The break is no less than 4ft. in width, and is made with great rapidity. Next week we shall give illustrations of this switch, in which Mr. Ferranti's accustomed ingenuity is markedly displayed. The main fuses are each

Digitized by Google

about two feet in length, and consist of tin wire, several fine wires being joined in parallel. They are mounted on plugs provided with long ebonite handles, by which they can be readily replaced. It is, however, a very rare event for a fuse to go off.

The main wires on the overhead circuit are all of 19/15 strand cable, insulated with rubber and braid, suspended by leather thongs from 17/16 steel cables. The thongs are about 7in. in length and ¾ wide. The steel wire is shackled off at each pole, and Johnson and Phillips's well-known oil-cup insulators are now exclusively employed. The insulation resistance of the line amounts as a rule to about 3,500 megohms per mile. On the roof of the gallery is a main derrick, of iron lattice work, erected by Messrs. Saxby and Farmer, designed for 12 separate circuits. On ordinary house-tops iron poles of 3⅜in. diameter are employed, and are let into cast-iron sockets in the usual manner; about 400 of these poles have been erected, and over 100 miles of wire have been run, whilst up to the present time not a single breakage has occurred. It need hardly be said that this is a result which reflects the highest possible credit on the engineering staff. All streets are invariably crossed at right angles. The return wire is carried over the same line at a vertical distance of 1ft. below the positive lead, and not the least disturbance is now complained of on adjacent telephone circuits. Branch wires are usually 7/16 strand, and house wires 7/20. The external house wires are enclosed in earthenware piping, which is usually let into the wall. Before joining the transformer they pass through a safety fuse and a main switch. The junction of the primary wires with the transformer is made at the bottom of a deep groove in the outer casing of the transformer, and can only be got at by a screwdriver of extra length.

The Ferranti transformer was described and illustrated in *The Electrician* of February 10th, 1888, page 346. On the consumer's premises they are enclosed in a fire-proof casing, and are fixed in cellars or outhouses, or wherever a convenient place can be found. With the exception of a slight mishap at Lord Brassey's residence, of which unduly magnified accounts were circulated, no trouble whatever has been occasioned by the transformers. The main switches in the consumer's premises are all of the double pole type, the break being made instantaneously on each side. It is, perhaps, not generally known that the spark on breaking an alternating current is decidedly smaller than that which is given by a continuous current under the same conditions. It is also a singular fact that under certain conditions and within certain limits the spark is more vivid with a small current than with a larger one. On these circuits it is a fact that with a 20-ampere current the spark is less intense than with one-quarter of an ampere. The insulation between the primary and secondary of the Ferranti transformer is remarkably high. The core is first wound round with several layers of linen soaked in shellac, each layer being allowed to dry slowly. An outer coating of shellac paper is put on, and over this the secondary coil is slipped. The primary coil is usually made in twelve sections connected in series, so as to distribute the potential as much as possible; the sections are separated by shellac paper. The primary is insulated from the secondary in the same way as the secondary is insulated from the core. The transformers are made in the following standard sizes:—2½ horse-power, 5 horse-power, 10 horse-power, 15 horse-power, and 20 horse-power. These figures are, however, merely nominal; Mr. Ferranti seems always to allow himself an ample margin, and we are assured that the 2½ horse-power size has easily carried a load of 61 16 candle-power lamps, which is about equal to 6 horse-power. As a rule, the transformers are designed for 100 volts at the secondary terminals. From these terminals the house wires are taken to the meter, and from the other side of the meter the wires are the property of the customer, and the responsibility of the company ceases.

By far the greatest number of the lamps supplied are 10 candle-power incandescents; there are, however, a few Sunbeams, and about 14 or 15 arc lamps. Most of the latter are employed by photographers in Regent-street, and are regulated by hand. The lamps outside the Haymarket Theatre are of the Brockie-Pell type, and are run two in series off a 100-volt transformer.

The adjacent illustration (Fig. 1) is taken from a photograph of the machine room, and shows the two large Ferranti dynamos. The curves of current output in Fig. 2 are of a very interesting character. It may be as well to add that the ordinates representing current may be interpreted in lamps on the basis of about 4,000 lamps for each 50 amperes of the primary current. The effect of last week's fog is very evident in the upper curve.

REVIEWS.

Central Station Electric Lighting: with Notes on the Methods used for the Distribution of Electricity. By KILLINGWORTH HEDGES. (London: E. and F. Spon, 1888.)

From an incidental remark in the preface, and also from the presence of a "glossary of technical terms," we gather that in the intention of the author this book is addressed to the non-technical reader. We are, however, inclined, on the whole, to think that Mr. Hedges would have been better advised if he had allowed his ambition to take a higher, if somewhat less extended, flight—that is to say, if Mr. Hedges could have been prevailed upon to confine himself to a descriptive account of the central stations at present existing in this country, together with some notice of the more important installations in Europe and America, the volume would almost certainly have been one upon which it would have been easier to have passed a favourable judgment. But since we have to deal with the book as it stands, we are bound to confess that the pages which are specially intended to assist the comprehension of the non-technical reader, and particularly the earlier part, are but little calculated to increase the scientific reputation of the author. Such definitions as these:—"Potential: a difference of E.M.F., or high and low tension;" "Current, alternating: the intermittent flow in two directions," are scarcely worthy of the distinguished inventor of the duplex cut-out. We confess also that we read with some impatience a remark such as that on page 9—"The arc light is now well understood to be caused by the extremely high temperature of the end of one or both the carbon electrodes." Similarly vague and pointless statements are sadly frequent upon the pages in which the author is dealing with first principles.

When, however, Mr. Hedges settles down to the description of particular installations we find a considerable improvement in style, and much information has been put together which our readers will find it convenient to possess in a form adapted for ready reference. The tabular statements giving numerical and other data relating to central stations in this country and abroad are of considerable value. It is, however, to be regretted that Mr. Hedges should omit all description of the dynamos and engines, or of the method of regulation—these are not unimportant details in connection with central station lighting. The following stations are described, with more or less detail, in the order given:—Paddington, Grosvenor Gallery, Eastbourne, Tivoli, Lucerne, Milan, Berlin, Temesvar, Kensington Court, and Vienna. We notice that Mr. Hedges is under the impression that the "divided-main" system of regulation, as designed for the Paddington installation, is a device of special utility. We presume, however, that Mr. Gordon himself no longer holds this view.

Kirchhoff's Laws and their Application. By E. C. RIMINGTON. (London: Alabaster, Gatehouse and Co. 1888.)

This is a little *brochure* of some 50 pages, reprinted from the columns of our contemporary, the *Electrical Review*, and is likely, we think, to prove very useful to students. The application of the laws of Kirchhoff, in the form in which the student usually finds them stated in the text-books, to finding the distribution of the current in a network of conductors, generally proves a very cumbersome process when the student is left to his own unaided ingenuity. Clerk Maxwell has, however, shown ("Electricity and Magnetism," Second Edition, Vol. I., page 274) how, by the introduction of the idea of "cyclic currents" for each closed mesh, and the application of determinants to the solution of the resulting equations, the process may be carried out in a systematic and more simple fashion. In a Paper read before the Physical Society in June, 1885, Dr. J. A. Fleming illustrated this method by several interesting examples, and he also extended the theorem to the

Digitized by Google

determination of the *resistance* between any given points in the network. In *The Electrician* of October 23rd, and two following issues in the same year, Dr. Fleming's Paper was treated in a somewhat simplified manner, and the elementary principles of determinants were explained. Mr. Rimington has now recast the subject in a form well adapted for the comprehension of those whose mathematical attainments are of the slenderest character, and he has added some theorems of his own which will be useful.

KENSINGTON COURT (DRAFT) LICENSE, 1887.

The following is the draft license which has been issued by the Board of Trade for the regulation of the supply of current from the Kensington Court central lighting station. This draft is, however, subject to reconsideration and amendment:

Regulations and conditions for securing the safety of the public, and for ensuring a proper and sufficient supply of electricity, made by the Board of Trade, under the provisions of the Electric Lighting Act, 1882, and the Kensington Court Electric Lighting License, 1887.

In these regulations, the words, terms and expressions to which, by the Kensington Court Electric Lighting License, 1887, meanings are assigned, shall have the same respective meanings, provided that in these regulations

The expression "the license" shall mean the Kensington Court Electric Lighting License, 1887.

The expression "the undertakers" shall mean the undertakers for the purposes of the license.

The following regulations are made subject to the power of the Board of Trade to make such further or other regulations as they may think expedient for the purposes above mentioned.

I.—REGULATIONS AS TO SAFETY.

1. The electricity shall be delivered to the poles on the consumer's premises in some manner free from risk of causing fire on the premises in question, whether such fire should or might be originated during or in consequence of a proper or improper supply of electricity, or by reason of the cessation of any supply, or should or might be partly due to any defective action of the lamps, motors, storage cells, conducting wires, or other fittings connected with the poles for the purpose of using the supply of electricity.

2. The poles, service lines, and other conductors connected with the service lines between the poles and source of supply, so far as they shall be on the consumers' premises, shall be completely enclosed in insulating cases, or thoroughly coated with insulating material, in such a manner that no part of them can be touched by any person without the removal of such case or coating.

3. Alternating currents shall not be used.

4. Where any portions of any electric lines belonging to the undertakers are exposed in such a position as to be liable to be struck by lightning, they shall be efficiently protected by lightning dischargers, of such a pattern and construction as may be from time to time prescribed or approved by the Board of Trade.

5. The difference of potential between any point of any electric line used for charging storage batteries and the earth shall not exceed 250 volts.

6. The difference of potential at corresponding points of the positive and negative conductors used as service lines to any consumer's premises shall not at any time exceed 115 volts, and no portion of such service line shall be at a potential differing from that of the earth by more than 230 volts.

7. The undertakers shall provide and fix to the satisfaction of the Board of Trade such apparatus as the Board of Trade may from time to time consider advisable, in order to prevent the limits of difference of potential for the time being prescribed by regulations from being exceeded.

II.—REGULATIONS AS TO SUPPLY.

Notice of Intention to Supply through any Distributing Mains to be given to Local Authority.

8. One week, at least, before commencing to supply electricity through any distributing main the undertakers shall serve a notice upon the local authority of their intention to commence such supply, and that the said main is ready to be tested.

Undertakers to provide constant supply.

9. From and after the time when the undertakers commence to supply electricity through any distributing main, they shall maintain in such main a current of electricity sufficient for the use of all the consumers for the time being entitled to be supplied from such main, and such supply shall, except so far as may be otherwise agreed upon, from time to time between the local authority and the undertakers be constantly maintained at such pressure as may be prescribed by the regulations for the time being in force. Provided that for the purposes of testing or for any other purposes which the Board of Trade may consider necessary for the efficient working of the undertaking, the undertakers may with the permission of the Board of Trade discontinue the supply of electricity at such intervals of time and for such periods as the Board of Trade may think expedient.

Pressure on Mains during Supply.

10. During the whole of the period when a supply of electricity is required to be maintained by the undertakers in the distributing mains under the license and these regulations (in these regulations termed "the hours of supply"), the potential at corresponding points of the positive and negative distributing mains shall differ at each point by a constant difference (in these regulations termed "the standard pressure") to be fixed as hereinafter specified. Provided that the undertakers shall be deemed to have complied with the requirements of this regulation so long as the difference in potential does not at any point vary more than 3 per cent. from the corresponding standard pressure unless changes in potential recur so frequently as to cause unsteadiness in the supply.

Limits of Standard Pressure.

11. The standard pressure may be different for different points of any distributing main, but shall not be such as to cause a difference of potential at any consumer's poles of more than one hundred and fifteen volts.

Fixing of Standard Pressure.

12. The "standard pressure" shall be fixed by the undertakers for every distributing main, and notice of the amount of such standard pressure shall be given to the local authority before the undertakers commence to supply electricity to consumers through such main, and shall not be altered except by permission of the local authority, and upon such terms and conditions as the local authority may impose, and after public notice has been given during a period of one month in such manner as the local authority may require of the intention of the undertakers to apply for permission to alter the same, provided that the undertakers may appeal against any decision of the local authority under this regulation to the Board of Trade, whose decision shall be final.

Supply to be given at one or more pairs of poles on consumers' premises.

13. The supply of electricity upon any premises shall (except by agreement) be given at one or more pairs of poles situated thereon, the respective poles of each pair being situated at a safe and convenient distance from one another, and being in connection respectively with the positive and negative mains, and the undertakers shall be responsible for the maintenance of such poles and any other lines, fittings, and apparatus belonging to the undertakers, or under their control, upon such premises in a fit and proper condition for supplying electricity; but the undertakers shall not be in any way responsible for any defects in the construction of any electric lines or fittings within such premises, whether for the utilisation of the electricity supplied or otherwise, where such electric lines or fittings have not been supplied by them, nor for any neglect in the maintenance of any such electric lines or fittings where they do not belong to the undertakers, or are not under their control.

Pressure at Poles on Consumer's Premises.

14. The resistance of the service lines by which the supply is given to any consumer shall not, except by agreement, be greater than would cause the difference of potential at the positive and negative poles on any consumer's premises to be less than the corresponding difference of potential at the point of junction of the distributing mains and service lines by which the said consumer is supplied by more than *one* per centum of the corresponding standard pressure, when the maximum current with which he is entitled to be supplied by the undertakers under the license is passing through such service lines, or such other percentage as may from time to time be approved of by the Board of Trade, either generally or in respect of individual cases.

MEETINGS OF SCIENTIFIC SOCIETIES, &c.

SATURDAY, November 10th.

PHYSICAL SOCIETY (London).

3 p.m. "On the Coefficient of Mutual Induction of a Helix and a Coaxial Circle." By Prof. J. V. JONES.

TUESDAY, November 13th.

INSTITUTION OF CIVIL ENGINEERS.

8 p.m. Ordinary Meeting. Paper to be read: "Friction Brake Dynamometers." By W. WORBY BEAUMONT, M.I.C.E. At this meeting the medals, premiums and prizes awarded at the close of the last session will be distributed by the President.

ROYAL VICTORIA HALL.

8:30 p.m. Lecture: "India." By Mr. HAROLD COX.

FRIDAY, November 16th.

INSTITUTION OF CIVIL ENGINEERS.

7:30 p.m. Students' Meeting. Paper to be read: "Experiments on Beams." By Mr. ED. C. DE SEGUNDO C.E.

Digitized by Google

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny.
Editorial, Publishing and Printing Offices:

No. 1, SALISBURY COURT, FLEET STREET, LONDON, E.C.

Telephone No. 2714.

All Communications to be addressed to "The Electrician," 1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to "The Electrician."

All letters intended for insertion in "The Electrician," or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.

"The Electrician" is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.

"The Electrician" is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.

SPECIAL NOTICE.

Owing to the increase in the number of pages of "The Electrician," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.	6 months.	12 months.
For Foreign Parts and Colonies:—	s. d.	s. d.	s. d.
Within Postal Union	6 6	12 6	24 0
„ Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	14 6	28 0
The rates for the United Kingdom remain as follows:—	5 0	10 0	19 6

TO ADVERTISERS.

"The Electrician" offers exceptional advantages to Advertisers. **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

Trade Advertisements *intended for the current issue must be handed in not later than First Post on Thursday morning.*

Small Prepaid Advertisements *(for Rates see page xi.) are accepted up to 4:30 p.m. on Thursday.*

TECHNICAL PRINTING.

"The Electrician" Printing and Publishing Company (Limited) *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

The Electricians' Directory.

Royal 8vo. Cloth Boards, 3s. 6d., post free 4s.

At the commencement of each year is issued The Electricians' Directory and Handbook. *The Directory was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

THE DIRECTORY FOR 1889 IS IN PREPARATION,

And new names and addresses are now being received.

VOLUME XXI. OF "THE ELECTRICIAN."

Volume XXI. of "The Electrician" is NOW READY,
Price 12/6, post free 13/6.

Cases for Binding Volume XXI. are Now Ready, Price Two Shillings; Post Free, Two Shillings and Threepence.

THE INDEX TO VOLUME XXI.

The Index to Volume XXI. is presented Gratis with the current number of "The Electrician."

Complaints of non-receipt should be promptly forwarded to the Publisher.

"ELECTRICITY, OUR DEFENCE."

Speaking at Islington on the 1st inst., Mr. Stanhope enumerated some of the various ways in which our coast defences should be improved; and he dwelt particularly upon the importance for this purpose of electrical submarine mines. Had the Secretary for War possessed the advantage of reading Captain Zalinski's lecture, delivered a few days before in New York on a similar subject, his recommendations would have been possibly more emphatic, and his confidence in electrical defences still more pronounced. Captain Zalinski, of the United States Army, is best known in England in connection with the famous dynamite gun, of which we shall have to say more presently; but his lecture at the Electric Club was devoted to a general survey of the ways in which electricity has been adapted to the appliances of warfare, or, more exactly, of the improvements effected in those appliances by the application to them of electrical science. The title of his Paper was "Electricity as used in Sea Coast Defence," but with their usual felicity the American press have re-named it "Electricity, our Defence," a title which is so truly appropriate here that we have not scrupled to place it at the head of this article.

Captain Zalinski classifies his electrical subject roughly as follows: Military telegraphy; range and position finding; lighting; motors; manipulating guns; directing torpedoes; igniting mines and firing torpedoes and guns. In the last named of these the lecturer probably included the ignition of gun charges, as is done in the case of the pneumatic dynamite

Digitized by Google

gun, the projectile of which carries its own batteries and is exploded electrically either by contact with water, or by making electrical contact on concussion against a solid substance. The best form of fuse was of such importance in connection with this invention that some very exhaustive and valuable experiments were carried out in conjunction with General ABBOT, U.S.A., and other gentlemen, resulting in the adoption of a low-tension fuse of platinum-iridium being selected for the bridge, as having a higher resistance and lower specific heat than pure platinum. It is with fuses of this character that the charge of the pneumatic gun is exploded. The problem in this case was to protect the filament from rupture prematurely, but Mr. SMITH, Captain ZALINSKI's assistant, has succeeded in making a bridge solidly embedded in a pellet of compressed powder. Protected in this way it is possible to use the electrical fuse in an ordinary gunpowder shell. For the pneumatic gun two small batteries are enclosed at the rear of the charge, one dry, the other wet, and are ingeniously arranged so as to prevent accident, but to ensure their final action when once projected from the gun. The experiment with the "Silliman," a small vessel, 80 feet long, resulted in its complete destruction at a one mile range, after three or four rounds of dynamite had been discharged. The accuracy of the firing seems to have been remarkable, and in no instance did the shell fail to ignite.

With Captain ZALINSKI's description of the present condition of military telegraphy we need not trouble our readers here, as most of his examples are taken from English or German sources. A similar remark will apply to his interesting account of subterranean and submarine mines, full reports on the latest improvements of which have recently appeared in these pages. The great value of these appliances, however, for coast defence is insisted upon with much force of argument and illustration in Captrin ZALINSKI's lecture, and we commend it to the consideration of the naval and political authorities of this country. Naturally, Major WATKINS' range and position finder occupies a prominent place in the lecture; and a very good attempt is made to lay bare the secret for which the English Government paid £25,000, and is paying a ten years' annuity of £1,000. So long as the States keep on friendly terms with the mother country we shall always be pleased to hear that "American electricians could do quite as well in this field of ingenuity" as the English Major WATKINS. Just at present, however, we are rather glad they have not hurried themselves.

The merits and demerits of the electric light for revealing the position of the enemy are fully gone into by the lecturer, but with no very definite pronouncement. The Mangin projector is the form used in America; and it is urged that hand-regulation is preferable to automatic, in order to obtain any required length of arc, and for other practical considerations, especially on shipboard. With much greater confidence does the author speak of the employment of the electric motor for the working of guns, a method which he rightly argues is far superior to hydraulic or pneumatic machinery in point of safety and efficiency. Captain ZALINSKI cordially approves of a suggestion to work the dynamo for electric lighting of military trenches by horse-power. The dynamo and horse-power apparatus would be comparatively light and easily transported. It is interesting to note that Major G. S. CLARKE, of the Royal Engineers, is credited with this capital idea. Apparently the best American ideas on the subjects here discussed emanate from the corresponding branch of the U.S. army. On the importance of keeping up the technical and scientific training of the Engineering Corps Captain ZALINSKI is very emphatic, and he utters some much needed words of warning on the prevalent misunderstanding as to the simplicity of submarine mining, and the ease with which it is supposed to be capable of being improvised. The problem of harbour and coast defences is, to quote his own words, "complex in character, requires the greatest care in the preparation of material and in the training of the *personnel* to manipulate it. Every detail must be carefully prepared; there must not be a single weak link in the chain, or the system is likely to fail." The author gives us credit for being ahead of the States in these respects; but none the less, at a time when we are extending our system of defences, the conditions on which their usefulness depend should be constantly kept in view. The sufficiency of the appliances themselves, and the part played in them by electricity as shown in Captain ZALINSKI's Paper, would justify us in saying that, properly directed, they can hardly fail to secure for us that immunity from external assault concerning which the recent naval manœuvres left us with some misgivings.

OURSELVES.

It has been our custom not infrequently at the commencement of a new volume of this journal to congratulate its readers on the development and progress of electrical industry as exemplified in the pages of THE ELECTRICIAN during the past year. Established more than ten years ago, when electrical research was beginning to be turned to many practical purposes besides those of telegraphy, to which previously it had been chiefly confined, THE ELECTRICIAN has steadily promoted and been closely identified with these later developments, and may now claim to be the representative organ of the professions, manufactures and trades which are classed under the heading "Electrical." On the present occasion no apology is needed for reverting to the custom above-mentioned, the past year having been an exceptionally encouraging one as touching ourselves, and also, we have reason to believe, for those whose interests it is the privilege of this journal to promote and defend. From time to time, as the area of its influence became widened, THE ELECTRICIAN has been enlarged and its contents improved. A notable instance of this occurred twelve months ago, when, under new editorial and managerial supervision, THE ELECTRICIAN took a step far ahead of anything ventured upon before. Not only was the journal greatly increased in size, but an endeavour was made to raise the tone and to increase the usefulness of its contents. No effort has since been spared to supply our readers with original contributions from the leading scientific and practical electricians of the day, and to carefully record the discoveries and advances which have been made both in America and on the Continent of Europe. That these efforts have been appreciated we have assurances from all quarters of the globe where THE ELECTRICIAN circulates; assurances which find substantial confirmation in its largely extended sale and its increased advertisement columns. If, as we have said and believe, the progress of electrical industry coincides with the prosperity of its leading representative in the press, our clients have as good reason as ourselves to be more than satisfied with the past year's work.

The part which the Electrical Press has played in the directing and aiding the revival and extension of electrical business can hardly be exaggerated. The wider publicity given to the discoveries of science and the applications of invention have immensely hastened their practical adaptation to the needs of society, so that what was once an isolated and localised advantage is nowadays instantly made the property of the whole world. Science and practice are also in this way made to react upon each other; and it is not too much to say that the promptitude with which scientific lessons are taken up and

Digitized by Google

turned to account has vastly quickened the activities of pure science to an extent never before experienced. The attention now being devoted to electrical research is quite unprecedented in the annals of science; and its utilisation to mechanical and practical appliances is hardly less remarkable. No better evidence of this can be found than in the increased bulk of the ELECTRICIANS' DIRECTORY for the current year; and this will be still further demonstrated in the forthcoming volume, which is now being prepared. The formation of an Electrical Section in the London Chamber of Commerce, and the change of its title by the Society of Telegraph Engineers, may be mentioned in this connection. The amplification of our own title, by the addition of the words "Journal of Electrical Engineering, Industry and Science," has therefore been fully justified. We may also point to the technical and industrial journals of this and other countries in proof of the high esti mation in which electrical inventions are now held. The fact is encouraging, but it by no means meets the real requirements of the electrical world—requirements which must be satisfied by the fullest scientific as well as the soundest technical information. This can be provided only by organs devoting themselves exclusively to the subject, and of these it has been our ambition—in which we believe we have succeeded—that THE ELECTRICIAN shall be the foremost. As an electrical authority it has long occupied this position among technical journals; and as a trade organ, with a circulation now greatly in excess of any other English electrical paper, its standing cannot be gainsaid. It is in no spirit of idle boasting that we put these simple facts before our readers at the present moment. To them it is a matter of greater importance even than to us. We have always held that their interests were closely bound up with those of THE ELECTRICIAN, and what we are now saying is substantially this, that our friends have frankly admitted the fact by affording that support and patronage without which no journal can continue to exist. Our prosperity, we take it, is a mark of their contentment; and in congratulating ourselves we are congratulating them. Those efforts which we have made in the past will not be relaxed in the future. The series of portraits which have appeared with this journal will be continued from time to time, and we feel great pleasure in announcing that a portrait of SIR WILLIAM THOMSON, the first President of the newly-named Institute of Electrical Engineers, is now in preparation. Allusion has already been made to the publication in these pages of reports from foreign countries relating to electrical affairs. Our regular weekly letter from the United States, where the greatest activity prevails in all branches of electrical industry, has been highly valued; and steps are being taken to obtain similar letters more frequently than at present from responsible correspondents in the chief European centres.

One other change connected with the proprietorship of this journal it may be well to mention here. The reprinting in book form of Papers contributed to THE ELECTRICIAN, the publication of the ELECTRICIANS' DIRECTORY, and the preparing of new books placed with us for publication, had grown into a business of such importance, that a somewhat more definite title was needed to designate the printing and publishing establishment of which THE ELECTRICIAN newspaper is the central figure. The ownership of the paper has in no other respect changed; but its proprietors, for business purposes, have thought it more convenient to assume the position which the law permits in such cases, and they are now known as THE ELECTRICIAN PRINTING AND PUBLISHING COMPANY (LIMITED). Among the works which already have been published or are being prepared for publication by this Company may be mentioned Dr. FLEMING'S work on Alternating Current Transformers, Prof. EWING'S on the Magnetisation of Iron, Prof. PERRY'S Mechanical Construction of Dynamos, Dr. GORE'S Electrolytic Separation of Metals, Mr. WILKINSON'S Practical Notes for Electrical Students, Mr. BEAUMONT'S work on the Steam Engine Indicator, and several others. Lastly, we have made reciprocal arrangements with the leading American electrical journal, *The Electrical World* of New York, under which that periodical and its subsidiary publications are on sale at this office, and those of THE ELECTRICIAN COMPANY at the office of *The Electrical World*.

HERTZ'S RESEARCHES ON ELECTRICAL OSCILLATIONS.

BY G. W. DE TUNZELMANN, B.SC.

(*Continued from page 789, Vol. XXI.*)

Interference of the Direct Actions with those Transmitted through the Wire. If the square circuit B is placed at the null point in the second principal position, with the air space at its highest point, it will be unaffected by the waves in the wire, but the direct action when in this position was found to produce sparks 2 millimetres in length. B was then turned about a vertical axis into the first principal position in which there would be no direct action of the primary oscillation, but the waves in the wire gave rise to sparks, and by bringing P near enough to A, a sparking distance of 2 millimetres could be obtained. In the intermediate positions sparks were produced in both these ways, and it would therefore be possible to get a difference of phase, such that one should either increase or diminish the effect of the other. Phenomena of this nature were, indeed, observed. When the plane of B was in such a position that the normal drawn towards A A′ was directed away from that side of the primary conductor on which P was placed, there was more sparking than even in the principal position; but if the normal were directed towards P the sparks disappeared, and only reappeared when the air space was made smaller. When the air space was at the lowest point of B, the other conditions remaining the same, the sparks disappeared when the normal was turned away from P. Further variations of the experiment gave results in accordance with these.

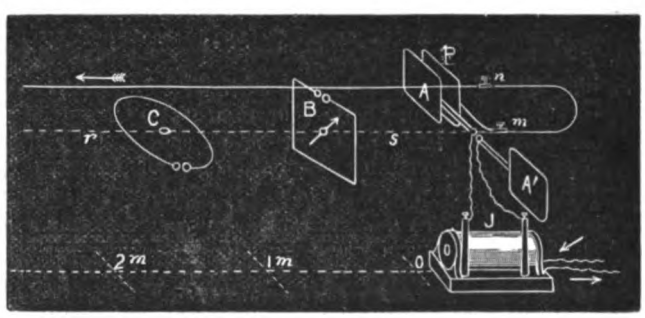

FIG. 11

It is easily seen that these phenomena were exactly what were to be expected. To fix the ideas, suppose the air space to be at the highest point and the normal directed towards P, as in Fig. 11. Consider what happens at the moment that the plate A has its greatest positive charge. The electrostatic, and therefore the total E.M.F., is directed from A towards A′. The oscillation to which this gives rise in B is determined by the direction of the E.M.F. in the lower portion of B. Therefore positive electricity will flow towards A′ in the lower portion, and away from A′ in the upper portion.

Consider next the action of the waves. As long as A is positively charged, positive electricity will flow from the plate P. This current is, at the moment considered, at its maximum value at the middle point of the first half wave-length. A quarter of a wave-length further from the origin—that is to say, in the neighbourhood of the null point—it first changes its direction. The E.M.F. of induction will here, therefore, impel positive electricity towards the origin. A current will

Digitized by Google

therefore flow round B towards A′ in the upper portion and away from A′ in the lower portion. The electrostatic and electrodynamic E.M.F.s are therefore in opposite phases and oppose each other's action. If the secondary circuit is rotated through 90 deg., through the first principal position, the direct action changes its sign, but not so the action of the waves, so that they now tend to strengthen each other. The same reasoning holds when the air space is at the lowest point of B.

Greater lengths of wire were then included between *m* and *n*, and it was found that the interference became gradually less marked, until with a length of 2·5 metres it disappeared entirely, the sparks being of equal length whether the normal were directed towards or away from P. When the length of wire between *m* and *n* was further increased, the distinction between the different quadrants reappeared, and with a length of 4 metres the disappearance of the sparks was fairly sharp. The disappearance, however, then took place (with the air space at the highest point) when the normal was directed away from P, the opposite direction to that in which the disappearance previously took place. With a still further increase in the length of the wire the interference reappeared and returned to its original direction with a length of 6 metres. These phenomena are clearly to be explained by the retardation of the waves in the wire, and show that here again the direction of motion in the advancing waves changes its sign at intervals of about 2·8 metres.

To obtain interference phenomena with the secondary circuit C in the third principal position the rectilinear wire must be removed from its original position, and placed in the horizontal plane through C either on the side of the plate A or of the plate A′. Practically it is sufficient to stretch the wire loosely and to fix it by means of an insulated clamp on each side of C alternately. It was found that when the wire was on the same side as the plate P the waves in it diminished the previous sparking, and when on the opposite side the sparking was increased, both results being unaffected by the position of the air space in the secondary circuit. Now it has been already pointed out that at the moment when the plate A has its maximum positive charge and at which, therefore, the primary current begins to flow from A, the current at the first node of the rectilinear wire begins to flow away from the origin. The two currents therefore flow round C in the same direction when C lies between the rectilinear wire and A, and in opposite directions when the wire and A are on the same side of C. The fact that the position of the air space is indifferent confirms the conclusion formerly arrived at, that the direction of oscillation is that due to the electro-dynamic E.M.F. These interferences are also changed in direction when the wire *m n*, 1 metre in length, is replaced by a wire 4 metres in length.

Dr. Hertz also succeeded in obtaining interference phenomena when the centre of the secondary circuit was not in the base-line, but these results were of no special importance, except that they confirmed the previous conclusions.

Interference Phenomena at Various Distances.—Interference may be produced with the secondary at greater distances than that of the null point, but care must then be taken that the action of the waves in the wire is of about the same magnitude as the direct action of the primary circuit through the air. This can be effected by increasing the distance between P and A.

Now, if the velocity of propagation of the electrodynamic disturbances through the air is infinite, the interference will change its sign at every half-wave length in the wire—that is to say, at intervals of about 2·8 metres. If the velocities of propagation through the air and through the wire are equal, the interference will be in the same direction at all distances. Finally, if the velocity of propagation through the air is finite, but different from the velocity in the wire, the interference will change in sign at intervals greater than 2·8 metres.

The interferences first investigated were those which occurred when the secondary circuit was rotated from the first into the second principal position, the air space being at the highest point. The distance of the secondary from the null point was increased by half-metre stages from 0 up to 8 metres, and at each of these positions an observation was made of the effects of directing the normal towards and away from P respectively. The points at which no difference in the sparking was observed in the two positions of the normal are marked 0 in the table below. Those in which the sparking was least, showing the existence of interference, when the normal was directed towards P are marked +, and those in which the sparking was least when the normal was directed away from P are marked −. The experiments were repeated with different lengths of wire *m n*, varying by steps of half a metre from 1 metre up to 6 metres. The first horizontal line in the table gives the distances in metres of the centre of the secondary circuit from the null point, while the first vertical line gives the lengths of the wire *m n*, also in metres.

TABLE I.

	0		1		2		3		4		5		6		7		8
100	+	+	0	−	−	−	−	−	0	0	0	0	0	+	+	+	+
150	+	0	−	−	−	−	0	0	0	0	0	+	+	+	+	+	0
200	0	−	−	−	−	−	0	+	+	+	+	+	0	0	0	0	0
250	0	−	−	−	−	0	0	+	+	+	+	0	0	0	0	0	0
300	−	−	−	−	0	+	+	+	+	+	0	0	0	0	−	−	−
350	−	−	0	+	+	+	+	+	+	0	0	0	−	−	−	−	−
400	−	−	0	+	+	+	+	0	0	0	0	−	−	−	−	−	−
450	−	0	+	+	+	+	+	0	0	0	−	−	−	−	−	−	0
500	−	0	+	+	+	+	0	−	−	−	−	−	0	0	0	0	+
550	0	+	+	+	+	0	0	−	−	−	−	−	0	0	0	0	+
600	+	+	+	+	0	0	−	−	−	−	−	0	0	+	+	+	+

An inspection of this table shows, in the first place, that the changes of sign take place at longer intervals than 2·8 metres; and, in the second place, that the change of phase is more rapid in the neighbourhood of the origin than at a distance from it. As a variation in the velocity of propagation is very unlikely, this is probably due to the fact indicated by theory that the electrostatic E.M.F., which is more powerful than the electrodynamic E.M.F. in the neighbourhood of the primary oscillation, has a greater velocity of propagation than the latter.

In order to obtain a definite proof of the existence of similar phenomena at greater distances Dr. Hertz continued the observations, in the case of three of the lengths *m n*, up to a distance of 12 metres, and the result is given in the table below:—

TABLE II.

	0	1	2	3	4	5	6	7	8	9	10	11	12
100	+	0	−	−	0	0	0	+	+	+	+	+	0
250	0	−	−	0	+	+	0	0	0	0	−	−	−
400	−	0	+	+	0	0	−	−	−	−	0	0	0

If we make the assumption that at the greater distance it is only the E.M.F. of induction which produces any effect, the experiments would show that the interference of the waves excited by the E.M.F. of induction with the original waves in the wire changes its sign only at intervals of about seven metres.

In order to investigate the E.M.F. of induction close to the primary oscillation, where the results are of special importance, Dr. Hertz made use of the interferences which were obtained when the secondary circuit was in the third principal position, and the air space was rotated through 90deg. from the base line. The direction of the interference at the null point, which has already been considered, was taken as negative, the interference being considered positive when it was produced by the passage of waves on the side of C remote from P, which makes the signs correspond with those of the previous experiments. It must be borne in mind that the direction of the resultant E.M.F. at the null point is opposed to that of the E.M.F. of induction, and therefore the first table would have begun with a negative sign if the electrostatic E.M.F. could have been eliminated. The present experiments showed that up to a distance of three metres interference continued to occur, and always of the same sign as at the null point. It was unfortunately impossible to extend these observations to a greater distance than four metres, on account of the feebleness of the sparks, but the results obtained were sufficient to give distinct evidence of a finite velocity of propagation of the E.M.F. of induction. These observations, like the former ones,

Digitized by Google

were repeated with various lengths of the wire $m\,n$ in order to exhibit the variation in phase, and the results obtained are given in the table below :—

TABLE III.

	0	1	2	3	4
100	−	−	−	−	0
150	−	−	0	0	0
200	0	0	0	+	+
250	0	+	+	+	+
300	+	+	+	+	+
350	+	+	+	+	0
400	+	+	+	+	0
450	+	+	+	0	0
500	+	+	0	0	0
550	+	0	0	0	−
600	0	−	−	−	−

which shows that as the distance increases the phase of the interference changes in such a manner that a reversal of sign takes place at intervals of from seven to eight metres. This result is further confirmed by comparing the results of Table III. with the results for greater distances given in Table II., for in the former series the effect of the electrostatic E.M.F. is eliminated owing to the special position of the secondary circuit, while in the former it becomes insensible at the greater distances owing to its rapid decrease with increasing distance. We should therefore expect the results given in the first table for distances beyond four metres to follow without a break the results given in Table III. for distances up to four metres. This was found to be the case, as is evident from inspection of Tables II. and III.

To show this more clearly the signs of the interference of the waves, due to the electro-dynamic E.M.F., with the waves in the wire, are collected together in Table IV., the first four columns of which are taken from Table III., and the remaining columns from Table II.

TABLE IV.

	0	1	2	3	4	5	6	7	8	9	10	11	12
100	−	−	−	−	0	0	0	+	+	+	+	+	0
250	0	+	+	+	+	+	0	0	0	0	−	−	−
400	+	+	+	+	0	0	−	−	−	−	0	0	0

From the results given in this table the author draws the following conclusions :—

(1) The interference does not change its sign at intervals of 2·8 metres. The electro-dynamic actions are therefore not propagated with an infinite velocity.

(2) The interference is not in the same phase at all points. Therefore the electro-dynamic actions are not propagated through air with the same velocity as electric waves in wires.

(3) A gradual retardation of the waves in the wire has the effect of displacing a given phase of the interference towards the origin of the waves. The velocity of propagation through the air is therefore greater than through a wire.

(4) The sign of the interference is reversed at intervals of 7·5 metres, and therefore in traversing this distance an electro-dynamic wave gains one length of the waves in the wire.

Thus, while the former travels 7·5 metres, the latter travels $7{\cdot}5 - 2{\cdot}8 = 4{\cdot}7$ metres, and therefore the ratio of the velocities is 75 : 47, which gives for the half-wave length of the electro-dynamic action $2{\cdot}8 \times 75/47 = 4{\cdot}5$ metres. Since this distance is traversed in 1·4 hundred-millionths of a second, the absolute velocity of propagation through the air must be 320,000 kilometres per second. This result can only be considered reliable as far as its order is concerned; but its true value can hardly exceed half as much again, or be less than two-thirds of this amount. In order to obtain a more accurate determination of the true value it will be necessary to determine the velocity of electric waves in wires with greater exactness.

It does not necessarily follow from the fact that in the immediate neighbourhood of the primary oscillation the interference changes its sign after an interval of 2·8 metres that the velocity of propagation of the electrostatic action is infinite, forsuch a conclusion would rest upon a single change of sign, which might, moreover, be explained, independently of any change of phase, by a change in the sign of the amplitude of the resultant force at a certain distance from the primary oscillation. Quite independently, however, of any knowledge of the velocity of propagation of electrostatic actions, there exist definite proofs that the rates of propagation of electrostatic and electro-dynamic E.M.F.s are unequal.

In the first place the total force does not vanish at any point on the base line. Now, near the primary the electrostatic E.M.F. is the greater, while the electro-dynamic E.M.F. is the greater at greater distances. There must, therefore, be some point at which they are equal, and since they do not balance they must take different times to reach this point.

In the second place, the existence of points at which the direction of the resultant E.M.F. becomes indeterminate does not seem capable of explanation, except on the supposition that the electrostatic and electro-dynamic components perpendicular to each other are in appreciably different phases, and, therefore, do not compound into a rectilinear oscillation in a fixed direction. The fact that the two components of the resultant are propagated with different velocities is of considerable importance, in that it gives an independent proof that one of them at any rate must have a finite velocity of propagation.

(To be continued.)

THE TESLA MOTOR AND WESTINGHOUSE STATION SWITCH-BOARD ARRANGEMENT.

As announced some time ago, work has been actively prosecuted, says the *Electrical World*, by the Westinghouse Electric Company in the construction of an alternating-current motor by which the value of the alternating system as a method of power distribution is largely increased. This new motor, which is illustrated in the accompanying illustration (Fig. 1), is based on the method of electro-dynamic rotation devised by Mr. Nikola Tesla,* and is so constructed that no commutator or contact brush of any kind is required, the armature being without any external electrical connection, and the rotative effort being exerted entirely from the changing polarity of the field-magnets.

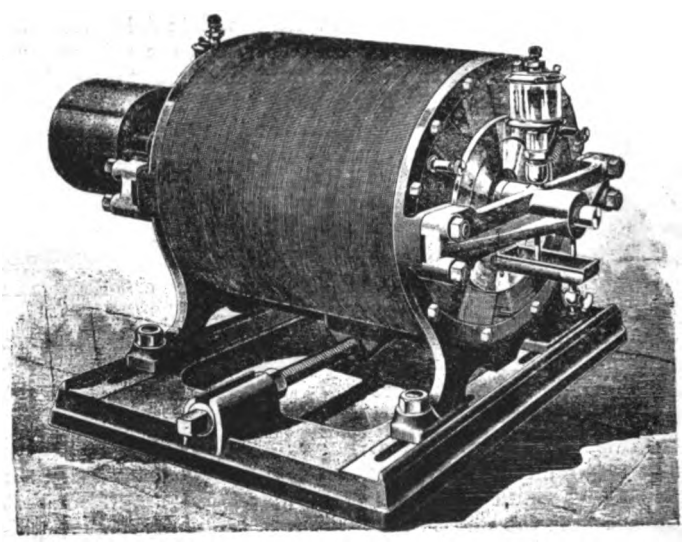

FIG. 1.

The New Westinghouse Alternating-Current Motor.

As will be seen, the motor consists of a series of field-magnets built up of laminated sheet iron and wound with two sets of coils, the ends of which are connected to the two binding posts shown. These binding posts form the only connection with the regular lighting circuits, with the addition of a single return wire. By the aid of this return wire two alternating currents are sent through the field of the motor at the same time, the pulsations of the two currents being equal in strength, but the one lagging a quarter phase behind the other in the two sets of field coils respectively.

* See *The Electrician*, June 15, 1888.

Digitized by Google

The effect of this is that a rapidly rotating polarity is given to the field, corresponding in period to that of the currents producing it.

The armature core of the motor is of the Siemens drum type, and it is wound with a comparatively few turns of heavy wire, the ends of which are soldered together, forming a closed circuit having no connection with the energising current. The alternating currents in the field induce secondary currents in the armature, and by the attraction between these and the revolving polarity of the field armature rotation is produced, the rate of rotation corresponding very nearly with that of the field. When no work is being done by the motor, the synchronism is exact, or nearly so, and very little current passes either through the armature or field, but as load is put on and the work increases, the armature tends to lag slightly, causing the passage of more current in proportion to the work done. The reaction between the armature and field is therefore similar to that between the primary and secondary of a converter when changes of lamp loads take place in the secondary circuit. The addition of the return wire for the motor circuit can be made easily, so as to adapt existing lighting circuits to motor work.

The speed of the motor, as well as its direction of rotation, may be regulated by an ingenious adaptation of the converter principle, an adjustable "choking coil" arrangement being employed, which avoids the use of resistances and switches. The simplicity of the winding and general construction of the motor makes it unlikely to get out of repair. Thus the insulation of the armature is of no importance, since the current induced in it, though comparatively large in volume, has a potential of but a few volts, and often less than a volt, regardless of the voltage of the supplying circuits.

The standard station switch-board arrangement adopted by the Westinghouse Company is shown in our illustration (Fig. 2), which represents a board arranged for two dynamos and four lines, any greater number of lines or dynamos simply involving an extension.

Digitized by Google

Commencing at the bottom of the switch-board there are four rheostats, the two small ones nearest the centre being in the field circuits of the exciters. The general practice, as is well known, is to provide each dynamo in such a station with an exciter of sufficient capacity to furnish current to both dynamos. Only one exciter is therefore in service at any one time. It follows, therefore, that the governing of the whole station is performed by the movement of the handle of one only of the two smaller rheostats, the other one being for the time out of service. The two larger rheostats are respectively in the field circuits of the two dynamos, and are used only when it is necessary to equalise their voltage for varying loads, which with well-designed lines is seldom required. The regulation of the station in practice is therefore reduced to a slight movement of the handle of one of the smaller rheostats five or six times in the course of a night's run, with one or two adjustments of the larger rheostats to equalise pressure.

Two small changing switches between the rheostats are used for connecting either exciter with either dynamo at will, and the single small switch immediately over them is used for coupling the field circuits of both dynamos together. When the switches are closed, as shown, both exciters are running connected. This arrangement of the switches, therefore, gives complete control of the supply of exciting current, and prepares for any ordinary emergency.

Over the rheostats are shown four sets of trunk wires, each consisting of two heavy parallel copper rods. Between each upper and lower set are three changing switches. The wires leading to the middle connection of the centre switch come from the dynamo, whose current is, of course, transferred to either pair of trunk wires, according to the position of the switch lever. The two outside switches of each triplet control the two lines respectively, and transfer their connection to either pair of trunk wires as desired.

Between the horizontal sets of trunk wires there are placed two multiple arcing switches, by which the two dynamos may be connected to run together or may be separated at will. By this arrangement either dynamo can serve either line or combination of lines at will, and may be changed by a single movement without interrupting the continuity of the circuit.

Directly over the trunk wires shown there is placed a row of six safety-catch holders, each with double fuses and plug cut-outs. The object of these safety catches is to protect the apparatus behind them from short circuits on the line, and the double fuses provide a ready means for displacement without interruption.

Over the safety catches are placed four voltmeters each with its attendant compensator above it. Each voltmeter registers the voltage on its particular line, and the sole duty of the tender is to see that the needle on the voltmeter does not vary beyond the length of the dotted scale. The compensator, which is shown enlarged in Fig. 3, is in series with the voltmeter, and adjusted at the plug connections to the maximum number of lamps served from it and at a point-switch enclosed within its case to a tabular number depending on the drop in the line. In this manner the indications of the voltmeter are maintained correct for all loads, independent of the varying drop in the line.

Between each pair of voltmeters there is placed an ammeter which indicates the output of the current from the dynamo to which it is connected, and below each ammeter is a short-circuiting plug, which, when plugged in, admits of the ammeter being removed. Over each ammeter is a lamp for the general illumination of the switch-board, and at the top is a row of six small converters, through which the current is reduced for the voltmeter.

Besides the apparatus just described there are several adjuncts to a central station, such as lightning arresters and ground protectors, and a standard voltmeter by which those in daily use are maintained correct.

Our illustration (Fig. 3) shows the enlarged view of the "compensator" above referred to, and Fig. 4 illustrates the standard voltmeter. As it is frequently desirable to reduce the illuminating power of lamps on one circuit without interfering with others, such as in the sleeping apartments at night, the house-regulator shown in Fig. 5 has been designed. This is placed in circuit with each floor-branch of a house, and by setting the pointer, any desired amount of illumination can be obtained without interfering with the remaining lamps in a house.

Electricity in Agriculture.—Prof. Wollny, of Munich, has lately been conducting some experiments upon the action of an electric current on vegetation. The soil experimented on was divided into plots 4 metres square, plates of zinc 30 centimetres broad and 2 metres long being placed at opposite ends of each square. The line was carefully insulated, and five Meidinger cells were inserted in the circuit. The tests were kept up from seed time to harvest, but neither corn, potatoes, nor any other vegetable or cereal, were affected in the slightest degree.

THE FINANCIAL POSITION OF THE LONDON ELECTRIC SUPPLY CORPORATION.

The following is an extract from an article which appeared in *Money* of November 7th:—

We have made it our business to inquire into the position of the London Electric Supply Corporation Limited, of which a good deal has recently been written; and we have come to the conclusion that if ever the electric light is to be a commercial success, it should be so in the hands of this concern. This is not the place to give the history of this corporation, which is the outcome of Sir Coutts Lindsay's experiment of four years back in lighting the Grosvenor Gallery by electricity; but it may be remarked that the demands made upon the Grosvenor station, which was then installed, have increased so steadily that the present corporation has been formed, with an authorised capital of £1,000,000, to erect and equip the new central station at Deptford, from which the directors expect eventually to be in a position to supply the necessary current for 2,000,000 lamps, while they have already invited orders for the supply of electric current for execution early next year.

This is a large order, and some particulars of the corporation and its position will be found interesting. Of the nominal capital of £1,000,000, in £5 shares, rather more than half is at present subscribed, the precise figures being £535,000. The company is by no means a public company in the full sense of the word, for nearly the whole of its subscribed capital is held by eight-and-twenty principal shareholders, as will be seen from the list appended:—

Shareholders.	No. of £5 shares.	Amount invested.
Lord Wantage	45,000	£220,000
Hon. Reginald Brougham	1,148	5,740
Right Hon. Earl Crawford	2,694	13,470
Sir Coutts Lindsay	9,777	48,885
Ince, H.	1,084	5,420
Pyke, Joseph	4,041	20,205
Wade, A.	2,018	10,090
Lord Hillingdon	1,000	5,000

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *October 27th*, 1888.

The most important event during this week was the holding of the Seventh Annual Convention of the American Street Railway Association. A year or two ago the meetings of this body were devoted chiefly to the discussion of the care of horses, feed, the protection of hoofs, the different kinds of horseshoes, the disposition of manure, and other similar topics. But now the face of affairs has entirely changed; the veterinary surgeon is rapidly being replaced by the mechanical and electrical engineer, the horse is making way for the cable and the electric motor, and the consequence is that the discussions no longer deal with the horse as a noble animal useful to man, but are largely, if not wholly, concerned with questions relating to the utilisation of mechanical power and the care of machinery. This year the electrical delegation was so large as to excite general comment and attention. While the cable came in for its share in the proceedings, it must be said that electricity was

Digitized by Google

unquestionably the lion of the hour. Addresses were made by Mr. W. Bracken, of the Julien Company, on the subject of storage battery work, and by Mr. Barr, of Philadelphia, who had obtained some very satisfactory results there with a Wharton-Reckenzaun car; by Mr. Sprague and Mr. Mansfield, in regard to electrical systems in general, and more particularly the overhead method; and by Mr. R. W. Blackwell on working with conduits. In each department material progress was shown. Mr. Bracken gave an interesting statement with regard to the work done with the Julien cars on the Fourth Avenue-road, and convinced his hearers that the demonstration there not only meant something for the present, but was destined to have a great deal of influence in the future. The greatest interest in this particular installation appears to have been taken by the street railway men, who recognise very forcibly the fact that, after all, the storage car presents the fewest difficulties in the adoption of electricity for street car work in large cities. Mr. Blackwell's presentation on behalf of the conduit was also listened to with close attention, and from what was said by him it was evident that large advances have been made in this field as well as in the others. He made an announcement, too, of great importance, to the effect that the obstructions, legal and other, to work on the conduit road for Fulton-street, New York, had all been overcome, and that work would be begun forthwith to lay conduit for that road, equip the plant, and have the whole installation running before the new year.

Mr. Sprague, as usual, made a lively address, full of good points, on the subject of his road at Richmond and elsewhere, and gave details as to a good deal of new work which he has in hand. He stated that the road which he is now building in the suburbs of Boston for the West End Company, on the overhead system, would have twenty cars and two track-cleaning cars. The station would be equipped with 410 horse-power of steam, and 450 horse-power of dynamos. With that equipment sixty or seventy cars could be run, but only one engine would be started up for the initial equipment of twenty cars. He stated that in Richmond the proportion in the central station of horse-power per car on the road was about 5 or 5½ horse-power, and that at Harrisburg it ran up to about 6 horse-power, which was a good factor for large roads, but on smaller roads 8 to 10 horse-power per car was safer. Mr. Sprague exhibited at Washington the new truck which he has adopted for his street car work. The new motor differs from the old Sprague motor employed for cars in being a single horizontal U-shaped machine, with the cores flattened so as to clear the ground as much as possible, the lowest point being only 9in. below the centre of the axle. Each car carries two of these motors mounted on the usual Sprague method, having two bearings on the car axle, and a flexible spring connection with the car body. Power is transmitted from the armature to the car axle by two sets of gearing, with a total reduction of 12 to 1. No oil cups are used about the motor, all the bearings being self-oiling, and requiring attention but once a day at most. These bearings have also a special dust-guard attachment to keep the oil from working out and the dust from working in. The whole machine and gearing are enclosed in a tight rectangular boxing which is attached to the motor, and moves with it. Each motor will take a steady load of 12½ horse-power, and will work easily up to 15. These new types of motors and cars will be used, I understand, in all the coming Sprague street railway work. The Thomson-Houston Company had the advantage of being able to exhibit in Washington a new electric railroad in full operation. Under the supervision and direction of Captain Griffin, U.S.A., and Mr. G. W. Mansfield, work on the road was rushed through at a tremendous pace, and in spite of the lateness of the date at which consent was obtained from Congress, which, as you probably know, runs the city of Washington as a sort of pocket borough, the road was in readiness for the delegates to see how it worked.

One special feature about the road is that over a long stretch at the beginning the poles are set right down the middle of a broad avenue, so that the brackets carrying the overhead wire stand on each side of the pole. At every third pole there are groups of incandescent lamps, red and white, which when lit up at night practically illuminate the avenue. This piece of work is reported as quite trim and handsome, and as being really an ornament to the thoroughfare. On another portion of the road poles are set on one side, and the overhead wire is carried on brackets; and on a third portion the wire is suspended down the middle of the road between two lines of poles. The road is at present nearly two miles in length, and is rapidly being extended. Three or four cars of the Thomson-Houston type, with twin motors, are in operation, and four or five more are to be added. As may be imagined, all this talk and exemplification of what could be done made no small impression on the Convention, and this was shown in a somewhat amusing way. On the second day one of the delegates, who looked like a very good judge of horseflesh and such excellent things, got up and objected warmly to all this talk about cables and electric motors. He had been running a horse car road for some time, and did not make money out of it, and what he had come to the Convention for was to learn how to do so. He thought the members would be using their time better if, instead of discussing the relative advantages and disadvantages of the storage battery and the overhead system and the conduit, they told him how much hay he ought to give each horse, how to keep their coats in good condition, and how to cool them in the summer and to keep them warm in winter. The appeal was wasted on inattentive ears, however, and instead of showing how well acquainted they were, or once had been, with veterinary practice, the members to a man laughed at their friend and trooped off to lunch. After lunch the advocate of the horse was again on his feet, and made another effort, but with no more success than at first. Little things like these show which way the wind is blowing.

The Westinghouse Electric Company have distinguished themselves this week on the top of their tremendous sensation of last week by publishing undoubtedly the finest catalogue ever issued in this country by an electrical light corporation; in fact, so far as I am aware, it will stand comparison for beauty and completeness with any work of the kind in any line of industry. It is simply superb. It is not merely a collection of handsome engravings, nor simply a catalogue of the price list order, but it is essentially a good technical, well and even gracefully written description of the alternate system. As the electrical papers this week publish some of the cuts, and use more or less of the matter, you will be able to form an idea as to what this catalogue is, if you have not received a copy direct from the company. The work includes the Westinghouse alternating machine and exciter and converter, and the Shallenberger meter, descriptions of all of which have appeared. The new matter included with the old deals with such details as the lightning arrester, the compensator switch-board arrangements, regulators for the house and the stage, and last, though by no means least, the alternating motor of the now well-known Tesla type. It is a multipolar machine, and requires three wires. The motor consists of a series of field-magnets built up with laminated sheet iron wound with two sets of coils. The armature core is of the Siemens drum type, without the commutator, of course; the winding, however, is much simpler, and consists of a few turns of a comparatively small wire, the ends of which instead of being carried out to a collecting ring or any other form of sliding contact are soldered together, forming a closed circuit, having no connection with the energising current. The alternating currents in the field induce secondary currents in the armatures, and by the attraction between these and the revolving polarity of the field rotation is produced, the rate of rotation corresponding very nearly to that of the field. When no work is being done by the motor, the synchronism is pretty nearly exact, and very little current passes through either the armature or the field. As the load increases, the armature tends to lag slightly, causing the passage of more current in proportion to the work done. The reaction between the armature and the field is similar to that between the primary and secondary coils of a converter, and the increase of load on the motor causes an increased supply of current in exactly the same manner as when lamps are added to the secondary circuit of a converter. This motor may be regulated in speed, and in-

Digitized by Google

stantaneously reversed in its direction of running, without the use of switches or resistance coils, and the machine altogether seems to have many recommendations in the department of electric power. The pamphlet concludes with a description of the Westinghouse alternating central station at East Liberty, Pa., and with some very interesting "bits of experience." The East Liberty station has lamps running at a distance of 4¼ miles from the dynamo, and the plant has a capacity of about 8,000 lights. It is stated that the permanent market for light which is secured on the first canvass in towns of moderate size averages about one lamp to each eight inhabitants, and that with the station running the demand grows steadily and even rapidly to a limit as yet undetermined. Other conditions being reasonably favourable, the incandescent light can compete with gas, and at a profit, it is stated, when the price of coal per ton is not more than double the current price of gas per thousand feet when no meter is used; but with a meter and a motor service the electric current can be supplied at rates which, if met, must prove unprofitable to the gas companies.

At the meeting of the American Society of Mechanical Engineers at Scranton last week, Prof. Elihu Thomson's process of electric welding was brought under consideration in a Paper by Mr. C. J. H. Woodburn, and the reception accorded it was at once cordial and encouraging. Mr. Jerome Wheelock reported that he had tried the method on screws, and found that the lead of the screw was perfect without any change, while the strength of the metal at the welded point was beyond question as great as ever. Mr. Oberlin Smith had tried the process himself with excellent results, and said that there was not even as much fear of burning the metal as with the blacksmith's fire. It did its work more neatly and uniformly, under much better control, and with a great deal more cleanness. Mr. R. W. Pope spoke of the advantages of the method in setting up electrical circuits, and Mr. Woodbury mentioned a method of making electric welded chains by machinery, passing the rods into the machine, where they are cut, bent and joined, then welding the chain in a thorough manner, and passing it out at the other end of the device.

Among other recent happenings of interest I should mention the lecture last week on "Electricity in Sea Defence," before the Electric Club, by Lieut. Zalinski, and a meeting this week of the New York Electrical Society at Mr. Edison's laboratory at Orange, N.J., when Mr. A. E. Kennelly delivered an interesting address on "Electrical Measurements."

NOTES FROM PARIS.

(FROM OUR OWN CORRESPONDENT.)

PARIS, *November 6th.*

The tenders for the lighting of the Halles Centrales have proved very numerous, no less than nine firms having tendered for the electrical plant and fifteen for the engine power. Among the former I notice the names of the Edison Company, M. Victor Popp (Thomson-Houston), the Société Lyonnaise (Brush), the Compagnie de l'Eclairage Electrique (Jablochkoff), and the Oerlikon Company of Zurich. Among the firms tendering for the engine and boiler power are Messrs. Belleville and Co., Babcock and Wilcox, Collet and Co., Boulet and Co., and Weyher and Richemond. All these proposals have been cursorily examined, and the general impression is that the £40,000 voted by the Conseil Municipal will certainly not be exceeded, and may not even be all required. A working sub-committee was immediately appointed, with instructions to lose no time in coming to a final decision, so that the works may be begun without delay. There is, therefore, every prospect that at the opening of the Universal Exhibition in May next the Halles Centrales and part of the streets around them will be lit by electricity.

The Syndicat International des Electriciens, of which M. Hippolyte Fontaine is the chairman, and which has contracted for the public and private electric lighting of the forthcoming Exhibition, has already fixed the number and position of the lights. The trees in the gardens are to be lit by 6,350 incandescents and the fountains by 104 arcs and 200 incandescent lamps, the Palais des Machines absorbing 346 arcs and 1,130 incandescents. The total will be no less than 1,300 arcs and over 10,000 incandescents, with an aggregate engine-power of 3,000 horse-power. The private lighting is expected to require another 1,500 horse-power at least. In these figures I do not include the 500 horse-power required for the lighting of the Eiffel Tower or the 300 horse-power for the gas engines. Great care will be taken in the fitting up of this colossal installation, and I have every reason to think that it will be one of the most perfect, if not one of the largest, in the world.

To intending exhibitors on your side of the Channel the proposed tariff of the Syndicat International des Electriciens may be useful. Fixing, maintaining, and lighting during the existence of the Exhibition 60fr. per 16 candle-power incandescent, 45fr. per 10 candle-power incandescent, 750fr. per 1,000 candle-power arc, 500fr. per 500 candle-power arc. These charges include the running of the conductors up to the lamps, the supply and renewal of the incandescent lamps, and the fixing, maintenance and renewal of the carbons in the case of arc lamps. These prices are calculated on the basis of a maximum of 900 hours, and will be charged even if this maximum is not reached. The money will be due, one-half on first lighting up and the second half three months after. After 900 hours the charges will be 4 centimes per 16 candle-power incandescent per hour, and 3 centimes per 10 candle-power incandescent per hour; while for arc lamps they will be 1fr. per 1,000 candle-power lamp per hour, and 75 centimes per 500 candle-power lamp per hour. All lamps will be extinguished after 11:30 p.m. The charges for current for motive power will be 50 centimes per horse-power-hour up to 500 horse power, and 40 centimes per horse-power-hour over that amount. The only two remaining regulations of any particular interest are the last clause and clause 7. The former provides that in case of disagreement between a consumer and the syndicate the matter shall in the last resort be referred to the Director-General of the Exhibition to adjudicate upon. Clause 7 runs as follows: "Should it happen that owing to *force majeure* the syndicate is under the necessity of temporarily cutting off the electric supply, the syndicate will not indemnify the consumers beyond repaying them the money collected for the supply they were unable to obtain."

The Palais Royal central lighting station is being actively pushed forward, and it is hoped that everything will be in its place by the end of this month at the latest. Considering the mass of earth to be excavated and removed, the rate of progress is certainly very creditable. When complete, the only sign of the existence of a central station in the Cour d'Honneur will be a magnificent candelabra, the light from which alone will suffice to illuminate all this portion of the building.

SCANDINAVIAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

COPENHAGEN, Nov. 5, 1888.

A central station for electric light is approaching its completion, this undertaking being independent of the large central station about the erection of which the gasworks of the town have been for some time negotiating with the corporation. The new central station now in course of construction is being built by the well-known firm of J. E. Ericson's Mekaniska Verkstod, Stockholm, who already, in the summer of 1887, started a small station for about 350 incandescent lamps. Stockholm taking kindly to the new mode of lighting, an extension was soon deemed advisable, and the company bought a larger site, where a new building has now been erected. It was intended to open the new station on October 1st, but some unexpected difficulties in connection with the building, the foundation having to go to a depth of 22ft., have caused some delay. The floor of the cellar, where the whole of the machinery is located is 16ft. below the street. The new central station has a capacity of 4,000 lamps. The cellar consists of two compartments, of which one contains four compound steam engines of 100 horse-power each, and the other four boilers of a similar capacity. Both engines and boilers have been supplied by the Atlas Engineering Company, Stockholm. On the ground floor are four huge dynamos from Siemens and Halske, each with a capacity of 1,000 incandescent lamps. The room with the dynamos is just above the engine room, the belting passing through apertures in the arched stone floor, which rests on iron girders. On the first floor are offices and residence for the officials. On the roof of the building is a good-sized iron framework, for the support and fixing of the cables. The Ericson Company has recently sold the whole establishment to a new company, which has been formed under the style of Stockholm's Elektriska Belgsiringsaktiebolag, in which the old company, however, holds the largest number of shares. Subscribers for more than 2,000 lamps have already been secured, among them being the Crown Prince's residence at the Castle, as well as some of the principal reception rooms of the King and Queen of Sweden, several banks, Government offices, insurance companies, restaurants, &c.

The new building of the *Aftonbladet* newspaper has been fitted with electric light. The installation comprises about 140 16-candle incandescent lamps; the dynamo is from S. Schuckert, Nürnberg, with a capacity of 210 lamps, being, besides, able to feed an accumulation battery of 54 elements, which can supply current when the dynamo is not being worked for 56 16-candle lamps for 6—8

Digitized by Google

hours. The dynamo is being worked by a two-cylinder high-pressure steam engine from Munktell's Engineering Company, Eskilstema. The regulating and coupling appliances, &c., for the electric light are most efficient, and the installation has altogether been effected in an able and satisfactory manner by the firm of Luth and Rosen, Stockholm.

The electric lighting at the Stockholm Telephone Company is about to be extended and a new boiler has just been fixed. It has been supplied by the Matala Engineering Company, and is to supply power for about a thousand lamps.

A large number of new installations in the provinces of Sweden are in the course of erection, both for the lighting of towns and on private premises. Among the towns which contemplate the adoption of electric light for street purposes is Linköping, where the gasworks are preparing a plan for the lighting of the town, and at Ostersund a private firm has taken the matter in hand. The Stockholm Elektriska Aktiebolaget is very busy at present, and among the places for which machinery is in hand may be mentioned Bergviks Wood Pulp Works; Blaukaholms Saw Mills; P. A. Blom, Arbaga; Boras Central Station for Electric Light; Brusafors Wood Pulp Manufactory; Falsterbo Bruk's dairy and other buildings; Falu Metal Extraction Works; Hjerpen Cellulose Manufactory, Iggesinid iron works, saw mills, and steam planing mills, Karlstad Engineering Company, Konga Wood Pulp Manufactory, Lilla Edet Wood Pulp Manufactory, Linköping Brewery, Linde Central Station for Electric Light, Mölnbaeka Wood Pulp Manufactory, Norrköping Weaving Company's Mills at Geyt, Olafström Steel Pressing Works, Stjarufors' Wood Pulp Manufactory, Strömsnäs Iron Works, K. A. Sundström, Lodberg; Sundleyberg New Engineering Company; Thurbo Wood Pulp Manufactory, Vesteros Gas Works Company's central station for electric light, and Vesteros Engineering Company. The dynamos for all these installations are made at the company's own works at Arboga, Sweden, under Venström's patent, and they have during the present year already delivered similar dynamos amounting to 400 horse-power.

Electricity has for several months been applied to tanning purposes in the tan goods of a Nordköping firm, Sweden, with very satisfactory results. By the new method the time required is being reduced; in some instances to the same number of days which it used to require months. Leather prepared in this manner is in every respect as good if not better than leather obtained by the old process, and the cost of manufacture is less. It appears to be the intention to extend the works.

The charge for inland telegrams in Sweden will, from the beginning of next year, be reduced to 50 öre (6⅔d.) for messages not exceeding ten words. A few additional alterations in the tariff will come into force at the same time. The charge for inland "press" telegrams will, as heretofore, be reduced to one-half; but the amount paid must not be less than 50 öre. For "express" telegrams the charge will after 1st January be three times the ordinary rate, whereas it only used to be double.

The Swedish State Telegraphs seem to watch the telephone movement with increasing jealousy, and show an inclination to interfere with the erection of new private telephone lines. This is the case with a private line which is being constructed between Stockholm and Vesteros, and which will probably have some difficulty in obtaining the necessary permission from the Government, if some excuse can be found for not granting it.

There are few, if any, capita's in Europe where electric light has made less headway than in Copenhagen. The Danes are in many respects slow and careful movers, but the principal reason for the long stagnation in electrical matters in the Danish capital is probably the fact that the corporation of the town own by far the largest and most important gasworks, so that the progress of electric lighting has been impeded through regulations the opposite of encouraging. To all appearances, a change is, however, impending, and the gasworks themselves are understood to be preparing a plan for electric lighting. In addition to this, the new company of Koefoed and Hanberg, Copenhagen, have applied to the corporation for permission to erect a central station in the principal square of the town, the area comprised in the proposed concession being the busiest and most central in the town. The Koefoed and Hanberg Company are, in this instance, co-operating jointly with the Allgemeine Elektricitäts Gesellschaft (Edison), Berlin, which arrangement ensures sufficient capital. Koefoed and Hanberg have also applied to the Theatre Royal authorities about including this large theatre in the working of their central station. Offers of electric lighting have also been made to the theatre by C. P. Jürzensen's electrical establishment, Copenhagen, in addition, I believe, to the heating and ventilation of the theatre. This firm has recently completed an installation at the Copenhagen Exchange. The motive power are two Otto gas engines of 12 and 8 horse-power, and the lamps number 140, averaging 16 candle-power. The switch-board is fitted with a safety contact, and everything has been done to ensure perfect safety.

CORRESPONDENCE.

ELECTRO-MAGNETIC WAVES AND THE PROPAGATION OF POTENTIAL.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In connection with the letters of Profs. Poynting and Lodge, which you print in your issue of the 2nd November, I believe that the following extract from a letter from Sir William Thomson (which I have permission to publish) will be of interest:—

"I don't agree that velocity of propagation of electric potential is a merely metaphysical question. Consider an electrified globe, A, moved to and fro, with simple harmonic motion, if you please, to fix the ideas. Consider very quickly-acting electroscopes B, B', at different distances from A. If the indications of B, B' were exactly in the same phase, however, their places are changed, the velocity of propagation of electric potential would be infinite; but if they showed differences of phase, they would demonstrate a velocity of propagation of electric potential.

"Neither is velocity of propagation of 'vector-potential' metaphysical. It is simply the velocity of propagation of electro-magnetic force—the velocity of 'electro-magnetic waves,' in fact.—Yours, &c., WILLIAM THOMSON."

Taking the second point first, it is, I think, clear that if by the propagation of vector potential is to be *understood* that of electric and magnetic disturbances, it is merely the mode of expression that is in question. I am myself accustomed to mentally picture the electric and magnetic forces or fluxes, and their propagation, which takes place at the speed of light or thereabouts, because they give the most direct representation of the state of the medium, which, I think, must be agreed is the real physical subject of propagation. But if we regard the vector-potential directly, then we can only get at the state of the medium by complex operations, and we really require to know the vector potential both as a function of position and of time, for its space-variation has to furnish the magnetic force, and its time variation the electric force; besides which there is sometimes the space variation of a scalar potential in addition to be regarded, before we can tell what the electric force is. Besides this roundaboutness, it implies a knowledge of the full solution, and if we do not possess it, it is much simpler to think of the propagation of the electric and magnetic disturbances, and I find that this method works out much easier in the solution of problems.

The other question will, I believe, be found to be ultimately of precisely the same nature. Start with the sphere A at rest, and the field steady, and consider two external points, P and P', at different distances. The electric force at them has different values, and the whole field has a potential. But now give the sphere a displacement, and bring it to rest again in a new position. Is the readjustment of potential instantaneous? I should say Certainly not, and describe what happens thus. When the sphere is moved, magnetic force is generated at its boundary (lines circles of latitude, if the axis be the line of motion), and with it there is necessarily disturbance of electric force. The two together make an electro-magnetic wave, which goes out from the sphere at the speed of light, and at the front of the wave $E = \mu v H$. Before the front reaches P or P' we have the electric field represented by the potential function, but after that it cannot be so represented until the magnetic force has wholly disappeared, when again we have a steady field representable by a potential function. It is difficult to see how to plainly differentiate any propagation of potential *per se*.

If the motion is simple-harmonic, there is a train of outward waves and no potential. I imagine that an electroscope, if infinitely sensitive and without reactions, would register the actual state of the electric field, irrespective of steadiness or not. By an electroscope, as this is a purely theoretical question, I understand the very simplest one, a very small charge at a point; or, say, the unit charge, the force on which is the electric force of the field.

Digitized by Google

When these things are closely examined into, if the facts as regards the propagation of disturbances (electric and magnetic) are agreed on, the only subject of question is the best mode of expressing them, which I believe to be in terms of the forces, not potentials.

But there really is infinite speed of propagation of potential sometimes; on examination, however, it is found to be nothing more than a mathematical fiction, nothing else being propagated at the infinite speed.

It will be understood that I preach the gospel according to my interpretation of Maxwell, and that any modification his theory of the dielectric may receive may involve a fresh kind of propagation at present not in question.—Yours, &c.,

November 5th, 1888. OLIVER HEAVISIDE.

ELECTRICAL THEORY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I should have liked very much to consider and discuss the questions of Electrical Theory raised by Prof. Poynting and Dr. Lodge, but I am too busy at present to attend to anything that can be put off, especially when it is already engaging such competent attention. There is one point, however, I would like to make clear, and that is that I must have expressed myself unclearly if it was supposed that I thought that Hertz had demonstrated the existence of the ether. I thought I said clearly enough that it was the time propagation of light that did so, and that what Hertz had proved was that electro-magnetic phenomena were due to this same ether. Some are so familiar with this conception that they have forgotten that the time propagation in non-conducting space of electro magnetic effects had never before been demonstrated, and until that was done a theory of action at a distance was not only possible but was existent as a serious reality. This is more than can be said of such sceptics as Prof. Poynting's "very disagreeable person," who would probably maintain that the stars are the reflections of our sun in the irregular confines of the ether, even if he did not go so far as to maintain that all the rest of mankind are but reflections of himself. I doubt that either of these suppositions can be disproved.—Yours, &c., GEO. FRAS. FITZGERALD.

Trinity College, Dublin, Nov. 1, 1888.

MAGNETISATION OF SOFT IRON.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The magnetometer employed by Mr. Tanakadaté in his valuable researches on the magnetisation of iron may be greatly improved for many purposes by winding a few turns of the solenoid circuit backwards round the magnetometer needle at such a distance as to just neutralise the field of the solenoid.

I have found this simple addition very convenient in practice, more especially when very small pieces of magnetic material are under test.—Yours, &c., SYDNEY EVERSHED.

2, Victoria-mansions, S.W., Nov. 6, 1888.

ELECTRO-CALORIMETRY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: If I rightly understand Messrs. Stroud and Haldane Gee's reply (*The Electrician*, November 2nd, p. 831), it amounts in substance to this:—Granted that the series arrangement is unstable, it is so over so small a range of temperature that under the conditions of experiment the error, if any, may be safely neglected.

Now I am perfectly aware that the series arrangement has been employed in several previous researches, and am, moreover, familiar with the substitution method; but it seems to me that the method, implying, as it does, a constant ratio of heating in the two calorimeters, assumes the wire to obey identically the same law of cooling in all the different liquids under comparison. In comparing the specific heats of water and oil I should anticipate that with, for example, equal power spent in the two baths the wire in the oil would require to be at a distinctly higher temperature than that in the water.

Let Messrs. Stroud and Haldane Gee shunt the two wires through a high resistance differential galvanometer, and they will obtain experimental evidence as to the truth or otherwise of the assumption of constant temperature.—Yours, &c.,

SYDNEY EVERSHED.

THE ETHER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The theory that ether is the medium of transmission for heat and electrical induction has been brought into great prominence by the recent important experiments of Prof. Hertz upon "electro-magnetic interference," the alternative theory of "action at a distance" being, as supposed, finally laid to rest. The great question now must be, what is the physical nature of this ether that is said to pervade all space? Can it be, like other matter, resolved into a collection of atoms, or does it consist of a homogeneous whole, without any break of continuity? If the former, then it appears to me that "action at a distance" asserts itself again, for we should have to believe that the transmission was due to some action *between the atoms* composing the ether, and it is immaterial, as far as the theory is concerned, whether the distance bridged be that between star and star or atom and atom, the variation in the two cases being simply one of degree. I should be very glad if others who have given this subject their attention, and who see the difficulty here expressed, would let me have the benefit of their opinion.—Yours, &c., W. P. GRANVILLE.

November 5, 1888.

TELEPHONE CALL OFFICE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The date, 1888, given in Mr. Munro's letter as that of the establishment of the first London Call Office, is no doubt a misprint for 1883. This enables the question of priority to be definitely settled against London, since in 1880 there was a Call Office in Edinburgh, at Hall's Cab Office, Hope-street, as well as two in Glasgow, one in the lobby of the Royal Exchange and the other at 134, Douglas-street. By 1882 there was not a town worked by the National Telephone Company which did not possess at least one call office.—Yours, &c.,

A. S. T. E. and E.

[We are indebted to our correspondent for calling our attention to the misprint. The date should, however, have been 1880, not 1883. The call offices in London were opened in April of the former year.—ED. *E.*]

TELEGRAPHY WITHOUT WIRES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Being very much interested in reading the account of Mr. Willoughby Smith's valuable researches in telegraphy without a metallic connection between ship and shore, I venture a few inquiries thereon.

In the experiment which Mr. Willoughby Smith describes in his letter, was the boat at sea an iron or wood vessel? and does an iron boat (such as are usuallyemployed for lightship purposes) give as satisfactory results as one composed of wood? I should have supposed that an iron vessel would tend to act as a derived circuit, and that, therefore, the signals would be materially less sensible than in the case of a boat made solely of wood, even if the copper plates be lowered right to the bottom.

I notice in the sketch of the experiment that the vessel was "end on" between the lines from shore. Would such satisfactory results have been obtained had she been "broadside on," with the surface of the plates correspondingly altered in direction?

Such changes of position would, I suppose, frequently occur in the case of a lightship.

I should also like to know whether the return signal "understand" was transmitted *electrically*. As far as I can gather at present it was not. In lightship telegraphy such signalling from the ship would, I take it, be even more necessary than that from the shore.

I have ventured these questions merely with a view to obtaining further knowledge on this very interesting and important subject, should Mr. Willoughby Smith find leisure and be disposed to supply it.—Yours, &c., CHARLES BRIGHT.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In connection with Mr. Willoughby Smith's letter on the above subject in your issue of the 2nd inst., the following facts may perhaps be interesting to your readers:—

From this office—75, Queen Victoria-street, E.C.—we have an overhead telephone line to 59, Knightrider-street, a distance of about 110 yards. This line crosses several others nearly at right angles, but excepting a duplicate wire of our own which is not in use there are, at all events above ground, no parallel lines within considerable distance, and as the houses are high, underground wires, if any exist, are much too far off to produce any appreciable inductive effect, even if they were sufficiently parallel, which, owing to the line of the buildings, could scarcely be the case.

Under these circumstances it would be natural to expect that our line would be a quiet one and free from inductorial effect, but this is very far from being the case.

With a sensitive telephone receiver in circuit there is at all times a perceptible boiling noise, which is increased in wet weather, and is probably due to currents leaking from neighbouring wires—very likely at the insulators, some of which are on the same chimney as our own—and occasionally actual talking can be distinguished, though so faintly that only in very rare instances can the actual words be understood.

These constant noises are exceedingly faint, and can usually only be detected with sensitive instruments and acute ears. Not so, however, a very perceptible sound of peculiar rhythm which periodically occurs, and which under favourable conditions is loud enough to be detected with the telephone an inch or more from the ear.

When the line was first erected—about a year ago—I used to put down this peculiar sound also to leakage from neighbouring wires, and supposed that the regular rhythm was probably caused by one of the Exchange Telegraph Company's news printing instruments, with which very heavy currents are, I believe, employed.

Some time ago, however, an official of the General Post Office, who happened to call and who heard the effect, informed me that there would be no doubt that the sound was due to a Wheatstone automatic telegraph, as he could clearly detect both the plain reversals and the broken currents peculiar to that instrument.

Now, I understand that Wheatstone automatic instruments are only used by the Post Office, and that all the Post Office lines in the neighbourhood are underground and at such a distance from our line that induction could not possibly account for the loudness of the interference. It seems probable, therefore, that the effect would be due to an action similar to that which Mr. Willoughby Smith described, and that the sound we hear would be caused by a portion of the return currents of the Wheatstone circuit being diverted from the ground and flowing through our line, which is earthed at one end on the water main and at the other on the gas pipes.

Our wire being of No. 16 B.W.G. copper is of very low resistance, but the telephones employed have some thirty or forty ohms, and the resistance of the ground in the 110 yards intervening between our two earths must apparently be sufficient to bear an appreciable comparison to this, so that a small proportion of the Wheatstone current prefers to pass through our line and instruments rather than directly through the ground.

Considering the small intervening space between our two earths, and the probability that the distant earths of the Wheatstone circuit is many miles off—the General Post Office, where I presume the near earth is located, is some 300 or 400 yards distant in direct line—this result is certainly not a little remarkable.

I need only add that since we can always tell the moment the Wheatstone instrument starts or stops working, there would be but little difficulty in determining which particular instrument in the Post Office it is that we hear.

Of course the Wheatstone is too rapid to be read by sound, but the noise is I think quite loud enough to enable a skilled person to read the signals were an ordinary sounder with similar battery power substituted.

It appears to me that a great deal of what is now attributed solely to induction would be due to similar causes to the above, and that the subject is therefore well worth the serious attention of everyone connected with telephony.—Yours, &c.,

A. A. CAMPBELL SWINTON.

75, Queen Victoria-street, E.C., Nov. 6th, 1888.

RE BARNET ELECTRIC LIGHT.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: We notice in your last issue that you have copied a report of the "Barnet Local Board" meeting from the *Barnet Press*. That report is not accurate. The amendment proposed was to refer the whole matter back to the Lighting Committee for reconsideration, and that committee, after a personal interview with our Mr. Joel, sent in an amended report advising that our simple undertaking to complete the permanent work in as short a time as possible, should be accepted. This amended report was submitted to a full Board last evening, and was agreed to.

Kindly insert the above to correct any erroneous impression that there is any difference or dispute between the Barnet Board and ourselves.—Yours, &c.,

HENRY F. JOEL AND CO.

THE SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

At the meeting of the members of this Society held last evening at the Institution of Civil Engineers, the President (Mr. Graves) stated that the question of changing the title of the society had practically been decided by the result of the circulars which had been issued, and which, as already announced, had resulted in an expression of approbation from 837 members, with only nine dissentients. He, therefore, would content himself with moving a formal resolution to the effect that the title be changed from the Society of Telegraph Engineers and Electricians to that of the Institute of Electrical Engineers. On this being put to the vote, it was carried unanimously.

The members then adjourned to the Hall of the Institution, and after the usual formal business, Mr. W. LANT CARPENTER, B.A., B.Sc.. read the following paper:—

On Ocean Temperatures in Relation to Submarine Cables.

About a year ago (November 10, 1887), a valuable Paper was read before the Society, by Mr. Stallibrass, entitled "Deep-Sea Sounding in Connection with Submarine Telegraphy."

In that Paper, and in the discussion which followed, scarcely any reference was made to what is now known as "Temperature Sounding," and as some of the facts revealed by this process appear to have an important influence upon the electrical condition of submarine cables, I venture to think that they may not be without interest to the Society.

Reserving for a little the description of the methods employed for ascertaining deep-sea temperatures, I may point out that the deep-sea surveying expeditions, commenced in 1869, of H.M.S. "Porcupine," "Shearwater," and "Challenger," of the U.S. steamer "Tuscarora," and of vessels belonging to other Governments, have shown conclusively that the temperature of the great oceans may vary from 85° F. at the surface to 30° F., or even lower, at the bottom, in the tropics; and that the bottom temperature of inland seas of the same depth, such as the Mediterranean, Red, Celebes and Sulu Seas, is often very much higher.

A submarine cable, therefore, is liable to be exposed at various portions of its length to a range of temperature between 85° and 30° F. Such a cable is liable to be affected in two ways by alterations of temperature—(1) the resistance of the copper conductor; (2) the resistance of the insulation. I believe that the capacity of the cable is but little altered by changes in its temperature.

A copper conductor having a resistance of 9 ohms per knot (sea mile) at 50° F. would have a resistance of about 8·6 ohms at 30° F., and of 9·6 ohms at 85°, the exact figures being

30°	40°	50°	60°	75°	85°
8·632	8·803	8·974	9·144	9·40	9·57

or the increase of resistance is between 30° and 85°—10·8 per cent. of what it is at the lower temperature.

I am informed that in the case of the extremely pure copper wire prepared by the new Elmore electro-burnishing process (by which a film is burnished during its electro-deposition) which has a conductivity of 102·38 per cent. of the usual standard for "pure"

Digitized by Google

copper, the temperature coefficient is slightly higher than that given by Dr. Matthiessen for pure copper.

The insulation resistance is affected, however, to a very much greater extent, the exact figures being, in megohms per knot,

30°	40°	50°	60°	75°	85°
8085	4292	2308	1242	490	263

Hence the insulation resistance of a cable is more than thirty times as great at 30° F. as it is at 85° F.*

I hope that these figures will be considered enough to show the great influence of the temperature of the sea upon cables. I may add that all insulating materials are not equally affected. Thus, taking three cables, coated with different insulators, but each having an insulation resistance of 500 megohms per knot at 75° F., I am informed that at 28° F. the insulation resistance of gutta-percha would have increased to 12,850 megohms per knot, of Mr. Willoughby Smith's insulator to 15,200, and of Hooper's compound only to 1,590.

Although I do not propose to discuss the effect of the pressure at great depths, it may be as well to point out here, since the whole question of the effect of the sea upon the insulation resistance of a cable is under consideration, that Mr. Latimer Clark's formula enables this to be calculated, viz. :

$$R_p = R(1 + 0{\cdot}00023\,p)$$

where R is the resistance at atmospheric pressure, and R_p that at a pressure of p lbs. per square inch. An approximate datum for ascertaining this when the depth is known is that 800 fathoms depth gives a pressure of very nearly one ton per square inch.

Having thus shown the importance of a knowledge of deep-sea temperatures to the cable electrician, I will now describe the means adopted for ascertaining these temperatures. Prior to 1868 but very few isolated observations on this subject had been made, and the results were so remarkable that in many cases they were attributed to errors of observation. I believe that it was the present hydrographer to the Admiralty who first reported a bottom temperature of 31deg. in the Indian Ocean. The method of observation adopted was to fasten an ordinary self-registering thermometer to the sounding line, immediately above the machine which carried the detachable weight, to lower it to the bottom, and to read it when hauled up again, assuming that the lowest recorded temperature was at the bottom.

One reason why there was an inclination to reject the earlier observations was that they were inconsistent with the general idea propounded by Sir John Herschell in his treatise on Physical Geography "that in all deep seas a temperature of 39° F. will probably be found to prevail." This idea was founded on the assumption that sea water, like fresh water, attained its maximum density at 39 F. whereas, in reality, it continues to contract down to its freezing point, slightly below 28° F.

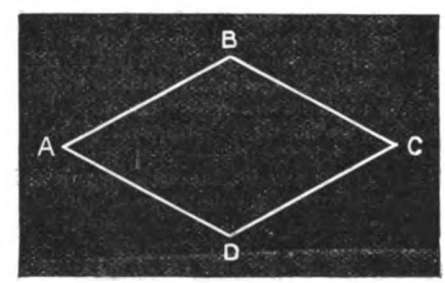
A real source of experimental error was, however, soon discovered ; the pressure of the sea at great depths, acting on the bulb of the thermometer, compressed it, and forced the liquid up in the stem, thus indicating too high a temperature. Several devices were proposed to obviate this ; the one finally adopted in 1869 being due to the suggestion of the late Prof. Wm. Allen Miller, admirably carried out by Mr. Casella, and hence the instrument is known as the Miller-Casella thermometer. It consists essentially of the ordinary Six's pattern of self-registering thermometer, but round the bulb is placed an exterior bulb, the space between the two being partly, though not entirely, filled with spirits of wine, a bubble of vapour being left. Numerous experiments made on shore with thermometers, with and without this protection, enclosed in iron boxes full of water, upon which hydraulic pressure to the extent of four tons per square inch was brought to bear, seemed to show that in this way the error due to pressure was eliminated.

In the spring of 1869 it was my good fortune to be a member of the deep-sea sounding and dredging expedition of H.M.S. "Porcupine," and to have, under Captain Calver, the first use at sea of these "protected bulb" thermometers. The general results I obtained were entirely confirmatory of those on shore. I prepared at sea a curve showing the differences of the indications between the protected and the ordinary thermometers, for a series of depths up to about 1,400 fathoms, and had the great satisfaction of being informed by Admiral Richards, who was then the hydrographer to the Admiralty, that this curve was exactly the same as one obtained on shore by means of the hydraulic press arrangement before alluded to. Since then these instruments have been most extensively used in deep-sea temperature sounding. Another form has since been constructed by Messrs. Negretti and Zambra, from suggestions kindly furnished to them by Commander Magnaghi, of the Royal Italian Navy. The neck of the bulb is contracted immediately above it, the contraction leading to a small reservoir ; the bulb contains enough mercury to partly fill the reservoir also. In using the instrument the bulb is in the usual downward position, and continues so until the sounding-line begins to be hauled up ; this reversed movement places the thermometer bulb upwards, the mercury breaks off at the contraction, and falls into what is now the lower part of the tube, when its length is measured on a scale, and the temperature at which its position was reversed is thus recorded. In deep-sea observations this reversal of position is effected by means of a fan working a screw, which releases the thermometer.

The Miller-Casella thermometer, however, from its extreme simplicity, is still largely employed in deep-sea observations in Her Majesty's Navy, and I am informed by the hydrographer to the Admiralty that the reversing apparatus of Messrs. Negretti and Zambra cannot always be depended upon in very deep water.

The "Porcupine" expedition, moreover, was supplied with a most ingenious device of the late Sir W. Siemens, for controlling electrically the results of the thermometric readings. I well remember my first introduction to him in the spring of 1869, to be instructed in the use of the apparatus, of which I was specially in charge. Through the kindness of Messrs. Siemens Bros. (Limited) I am enabled to show you the instrument to-night. It consists essentially of two coils of wire, similar in all respects, which form the two arms of a Wheatstone bridge. One of these is attached to a cable, and can be lowered to any desired depth in the sea ; the second, or comparison coil, being immersed in water on deck. The bridge is balanced, not by changing the resistances, but by altering the temperature of this water, and when equilibrium is obtained this temperature is read off by a thermometer, which is also the temperature of the submerged coil. Owing to the fact that the galvanometer furnished to us in 1869 was very far behind the beautiful marine galvanometer of the present day, it was only possible to make observations in exceedingly fine weather, when our small vessel of 400 tons was comparatively still.

To avoid the error which would be otherwise introduced by the leads to the resistance coil, the cable was constructed of a double core of insulated copper wire, protected by galvanised steel wire. One of the copper cores was connected to the arm B C of the bridge, and the other to the arm D C, and the steel wire served as the return earth-connection for both.



In the case of an instrument of this kind constructed for the American Government, and employed on board the surveying steamer "Blake" by Commander Bartlett, the resistance coil and comparison coil were made of silk-covered iron wire 0·15 mm. diameter, and each having a resistance of 432 ohms at 66° F. To allow the coil to be readily affected by changes in the temperature of the water, it was coiled on a brass tube with both ends open, allowing a free passage to the water. Sir William Thomson's marine galvanometer, with mirror and scale, were in this case employed to determine the balance of the bridge.

In a Paper by Sir William Siemens in the *Proc.* Roy. Soc. for June 15th, 1882, will be found the detail of a large number of comparisons, at various depths down to 800 fathoms, between the indications of this instrument and of the Miller-Casella thermometer simultaneously employed. The general result only is here given in Sir W. Siemens' own words :—

"The two instruments gave precisely the same readings at positions of maximum or minimum temperature, but in intermediate positions the electric thermometer, in almost every instance, gave a higher reading. This discrepancy may be accounted for, I think, by the circumstance that the electrical thermometer gives the temperature of the water actually surrounding the coil at the moment of observation, whereas the reading of the Miller-Casella instrument must be affected by the maximum or minimum temperatures encountered in its ascent or descent, which may not coincide with that at the points of stoppage. A strong argument in favour of the electrical instrument for geodetic and meteorological purposes has thus been furnished."

The physical, chemical, and biological results obtained by H.M.S. "Porcupine," in the North Atlantic, in the summer of 1869, and in the Mediterranean in that of 1870, were of sufficient interest to cause the fitting out and despatch of H.M.S. "Chal-

* I should add that these figures relate to the cable between Accra and Sierra Leone (African Direct Company), laid in 1886, and that Mr. H. D. Wilkinson has kindly assisted me in their calculation. The weight of copper in this cable is 130lb. per knot, which is also the weight of the gutta percha employed, and the sheathed deep-sea portion of the cable weighs 3½ tons per mile

Digitized by Google

lenger," for a systematic survey of the great oceans, which lasted for more than three years. The expedition left Sheerness on December 7th, 1872, and returned to Spithead on May 24th, 1876, having altogether traversed a distance of nearly 70,000 miles, and having established at intervals as nearly uniform as possible along the course traversed 362 observing stations, at each of which the bottom temperature was accurately ascertained, while at most of them the thermal stratification was determined by "serial temperature" soundings. The vessels of other Governments have also contributed a good share of observations.

The work of the United States ss. "Tuscarora," Commander George S. Balknap, however, deserves special notice here, because she was sent out by the United States Government, not with a view to scientific research, but for the purpose of determining by deep-sea sounding the most practicable route for a cable between the Pacific seaboard of the United States and Japan. In addition to the ordinary bathymetrical determinations, bottom temperatures were everywhere taken with Miller-Casella thermometers, and the thermal stratification was also determined down to about 600 fathoms by serial soundings. A very important body of facts was thus collected in regard to the thermal condition of the North Pacific along the two lines examined, viz., the southern route, passing directly across between the parallels of 20deg. and 30deg. N. lat. from San Diego, in California, by way of the Sandwich Islands, to the Bonin Islands, and thence north to Yokohama; whilst the northern route followed a great circle course from Yokohama along the line of the Kurile and Aleutian Islands to Cape Flattery, the northernmost point of the United States territory. Here such great depth of water, over 4,600 fathoms, was met with, having a bottom temperature of 32deg., that it was then deemed (1874) an impracticable route for a cable. During this cruise no fewer than 483 casts of the deep sea were taken, and the results were plotted in the same manner as those of the "Challenger," and embodied in a systematic account of the work, issued by the Hydrographic Office of the United States Navy, a copy of which I have here. The general result of all such observations, as regards the distribution of temperature in the open ocean, contrasted with that of seas more or less landlocked, such as the Mediterranean, I will now very briefly summarise.

By attaching thermometers to various points of the sounding line or wire it is possible to ascertain the temperature at various depths below the surface, as well as on the bottom. Such a set of observations made vertically over one spot is called a serial temperature sounding. The results of a number of such observations may be plotted upon a "Temperature Section," constructed upon two scales, a horizontal one of nautical miles, and a vertical one of depths in fathoms. The lines, more or less inclined to the horizontal, which are drawn through points of equal temperature, may be conveniently designated bathymetrical isotherms. In the diagrams before you the differences of temperature are indicated by coloured bands, as well as by lines—blue in various shades indicating water below 40°F., green and purple being used for water from 40° to 65°, while warm water is shown by various degrees of pink. [Diagram shown.]

I will call your attention first of all to these temperature sections across the North Atlantic, from Madeira through the Azores and Bermuda, to Halifax, Nova Scotia. You will observe, in the first place, that about two-thirds of the whole of this mass of water is 40°F., the bottom temperatures ranging from 34°·8 to 38°·7. You will also notice the *extremely* small bulk as shown by its sectional area of the true "Gulf Stream," *i.e.*, the superheated surface-laying of water issuing from the Gulf of Mexico, and, lastly, you will notice the continuity of the "cold wall" long known to the United States coast surveyors with the cold deep water of the Atlantic basin. This continuity was first traced, and the explanation of the phenomenon afforded, by H.M.S. "Challenger." In this diagram of the North Pacific, you will observe the same general condition of thermal stratification prevailing, but that there is a much larger proportion of colder water, and the bottom temperatures are even lower. In the next place, let us notice the facts in the equatorial Atlantic, where you will observe that the colder water comes nearer to the surface than anywhere else, and as the surface temperature is extremely high, the rate of fall in temperature is very rapid, and the isothermal bands are very narrow.

Speaking generally, these are very fair examples of the thermal stratification of any one of the great oceans, whose communication with the others is unrestricted, not only at the surface, but also to great depths below. But now let me ask you to compare with these diagrams some which represent the thermal stratification of such seas as are more or less landlocked; and as a good example we may take the Mediterranean, on the bottom of which so many cables lie. You will observe that, for the first 200 or 300 fathoms, the temperature falls in proportion to depth, in much the same way as it does in the Atlantic outside the Straits of Gibraltar, but that after that point, about 54° F., there is no further fall in temperature, notwithstanding that depths of 2,000 fathoms are reached, at which, in the Atlantic in the same latitude, and only a short distance west of Gibraltar, the temperature is 36deg. We shall presently see reason to believe that in this and similar cases two factors are concerned in the result—first, the average winter temperature prevailing in the locality; second, and most important, the depth to which there is free communication between these partially landlocked seas and the open oceans. In the case of some of these—the Red Sea, for example, whose only communication with the great oceans is through the shallow Straits of Babelmandeb—the mean winter temperature, or isocheimal, of the surface water has a considerable influence in determining the bottom temperature at great depths. The lowest temperature of this surface layer, even in its most northern part, is 71deg., and this temperature is uniformly carried down to the bottom at 450 fathoms depth. I am not aware of many deep-sea temperature observations, beyond those of Sir George Nares in the Gulf of Suez, having been made; but it may be pretty certainly affirmed that no lower temperature than this will be found, even on a bottom exceeding 1,000 fathoms depth, since the lowest surface temperature in the southern portions is never below 75deg., the highest being nearly 90deg. Yet, in the Arabian Gulf, the temperature at a depth of 2,000 fathoms is not above, and is very probably below, 36°·5.

A similar contrast is shown by the temperature soundings of Commander Chimnius between the temperature of the Sulu Sea (a small area between the N.E. of Borneo and Mindinao) and of the China Sea. The former, though only partially landlocked, is so shut in by reefs and shoals as to have only a very superficial and limited connection with either the China Sea or the Celebes Sea. Notwithstanding this inclosure, the depth is very great, ranging to 1,603 fathoms, and the following bottom temperatures, taken along the line of the submarine cable between Singapore and Hong Kong, make this point very clear:—

Sulu Sea.		Depth.		China Sea.
83°	.....	Surface	.....	84°
—	.....	30 fathoms	.....	77°
—	.....	50—80 ,,	.....	71°
64°·5	.....	100 ,,	.....	—
—	.....	200 ,,	.....	51°
51°·5	.....	308 ,,	.....	—
—	.....	416 ,,	.....	41°
50°	.....	500—1,603 ,,	.....	—
—	.....	673—1,546 ,,	.....	37°

The Sulu Sea was also examined very carefully by the "Challenger," in its relations to both the China and Celebes Seas. From 82deg. at the surface the fall is rapid to 60deg., but the isotherm of 55deg. lies at about the same depth as the isotherm of 50deg. in the China and Celebes Seas; below this the fall is still slower, so that the minimum of 50°·5 is only reached at 400 fathoms, from which depth to the bottom, at 2,550 fathoms, the thermometer continuously indicates 50°·5. Hence the condition of this sea closely resembles that of the Mediterranean. The influence of a still less complete seclusion from the polar under-flow is shown in the Celebes Sea, where the bottom temperature at 2,667 fathoms depth is 38°·5, while at nearly the same depth in the Indian Ocean, a little to the west of Sumatra, the bottom temperature was 32deg.

Again, a "Challenger" sounding between New Zealand and the Fiji Islands gave 32°·9 at 2,300 fathoms depth; but further west, towards Raine Island, at the entrance of Torres Strait, where the depth ranged from 1,350 fathoms to double that, the temperature never fell below the 35°·1 found at 1,300 fathoms depth, "which proves, undoubtedly," says Sir George Nares, "that below this depth the sea is cut off by a surrounding ridge, over which the greatest depth of water of any channel through it is 1,300 fathoms. As this is about the depth we found between the New Hebrides and the Fiji Islands, we may take it for granted that from Sandy Cape, in Australia, to New Caledonia, the New Hebrides, the Solomon Islands and New Guinea, there is a shallow bank with not more than 1,300 fathoms depth of water. Below this depth, in the hollow between the New Hebrides and Torres Strait, the water is comparatively stagnant, as in the Mediterranean and other cut-off seas."

What is the explanation of these remarkable facts, facts which have been verified over and over again, at various seasons of the year? The most probable one I believe to be (and there is much biological evidence in its favour as well as physical) that a constant vertical circulation of the waters of the great oceans is going on, sustained by differences of specific gravity, which are due, in the main, to differences of temperature. This doctrine was accepted by Sir John Herschell only three weeks before his death, and was also formally referred to by Sir George Airy in his Presidential Address to the Royal Society in 1872, as "certain in theory, and supported by observation." Speaking generally there is much evidence to show that in the Atlantic, Pacific and Indian Oceans the upper portions of the water in the northern hemisphere are moving in a north-easterly direction, while the lower layers are as constantly moving in a south-westerly direction. One very curious fact in support of this last assertion,

Digitized by Google

and of especial interest to us, is given in the *Proc.* Roy. Soc. for 1870, Vol. XIX., p. 218. A buoy which was attached to the Atlantic cable of 1865 broke away from the bulk of the cable, but carried with it a great length of the wire rope to which it was attached. Although the surface drift would have carried the buoy north-east of the spot where it was first floated, it did actually travel a long way to the southward, owing to the action on the surface of the long length of cable attached to it of the lower layers of water.

This great vertical oceanic circulation, then, is an illustration on a gigantic scale of the convection currents in liquids, with which we are all familiar in the hot water circulatory systems in use for heating public buildings. In the case of the ocean, however, there is reason to believe that the polar cold, at the surface, rather than the equatorial heat, is the prime cause of the movement. Into the discussion of that question, however, I must not enter here.

If this theory of a general vertical oceanic circulation be accepted the explanation of the phenomena presented by land-locked seas becomes at once apparent. They are more or less cut off by the surrounding barriers from this general circulation, and hence only receive a limited portion of the colder water. Thus, to take the case of the Mediterranean. The greatest depth of the Straits of Gibraltar (its only communication with general oceanic systems) is about 200 fathoms; the temperature of the North Atlantic outside at that depth is about 54deg., and hence no colder water than that can find its way into the Mediterranean, and accordingly in that sea we nowhere find a lower temperature than 54deg. The same explanation applies, with variations in depth, to the other cases I have mentioned in the Indian Ocean and elsewhere, and in many of these instances coral reefs appear to be the barriers which cut off the cold water supply.

The theory affords a reason, also, for the fact that under the equator the colder water is nearer to the surface than anywhere else in the tropics or sub-tropics. Here the two streams of polar water meet, the Arctic and the Antarctic, and owing to this a double volume of cold water is present, which wells up to the surface quite rapidly. I may mention that this point was foreseen and predicted by the proposers of the theory, before the observations were made; and subsequently these latter justified the expectations formed. There is, therefore, a continual ascent of glacial water under the equator; or, as has been well said, there is under the equator a belt of water which is colder than the water to the north and south of it.

It would be very interesting to trace the effect of this great system of oceanic circulation upon climate, and to discuss the evidence for its existence. Our Society, however, does not concern itself with such matters, and I must forbear. I have striven to lay before you, in very brief outline, the general facts of the distribution of temperature in the sea, and especially on the sea bottom where our cables lie, and to point out the influence of these temperature conditions upon the cables themseves. I venture to hope that those members who have special knowledge with regard to the influence of temperature upon cables will give us the benefit of that knowledge in the discussion which I trust will now follow.

An interesting discussion followed, in which Mr. Alexander Siemens, Mr. Chas. Bright, Capt. Wharton, and others took part. A full report will appear in our next issue. On the motion of the PRESIDENT, a cordial vote of thanks was passed to Mr. Laut Carpenter for his valuable Paper.

NOTE ON GEARING FOR ELECTRIC RAILWAYS.*

BY MR. ALMON ROBINSON.

Probably no one will be disposed to deny that in devising a connection for the motor and the car wheels, what Mr. Sprague attempted to do has been done extremely well. Has he attempted all that is desirable?

Mr. Sprague's investigations have shown that in street car work a very large percentage of the whole power used is expended in starting the cars. Now, it seems to me that a motor whose speed has a fixed ratio to that of the car wheels must work uneconomically when the car is moving slowly, for no amount of skill spent in varying the magnetic circuits can prevent an armature from wasting a current sent through it when it is practically standing still. It would seem, therefore, that wide variations of speed and load would make it necessary at times to weaken the field to an unprofitable extent. Perhaps, however, Mr. Sprague may be able to show that a properly designed motor will work with a high efficiency in doing anything which he puts upon it in railroading. But even in that case there would still remain the extra cost and extra weight of a motor large enough to lift its heaviest load by a dead pull. To do the hardest part of his work Mr. Sprague is really using a thing in which he disbelieves—a slow-moving motor.

In the storage car problem this matter of weight and bulk and cost becomes the most important element. Here the present practice is simply the hauling about of ten men to do by main strength what one man could do by a lever.

The desirability of a variable leverage for the motor has not escaped the attention of experimenters. In Mr. Henry's Kansas City work an arrangement of toothed gearing and clutches was tried. I have never learned whether this particular feature proved a help or a hindrance, nor whether it is in use on the Henry road said to be running at San Diego, Cal. A prominent inventor has expended a good deal of ingenuity on the details of a plan, making use of reciprocating friction pawls. Mr. Reckenzaun tried and abandoned a leather-covered chain clamped between two cones in such a way that the diameter of the circle of contact could be varied.

Mr. Van Depoele has suggested, and, I presume, tried, a connection having two different speed ratios, in which friction gears were used. For this particular purpose (furnishing a variable speed ratio) I am obliged to confess myself a believer in the possibilities of frictional gearing. For electric railroad work it is certainly under a cloud at present. Those who have used it most like it least. The eminent engineer who, about a year ago, read a Paper before the Institute on "Methods of Gearing," seemed to consider that it had been sent to its last resting place by the experts who tested some of Prof. Fleeming Jenkin's devices.

No one seems to notice that every day and on every railroad this method of transmission gets the roughest possible testing; that every locomotive pulls its train by frictional adhesion; that a rail and driving wheel are neither more nor less than a frictional rack and pinion. When we try to copy the work of the locomotive under other conditions our troubles begin; but no man who has ever seen a freight engine climb a grade has any right to speak with disrespect of frictional gearing.

The real root of all the difficulties with frictional transmission seems to be that the pressure producing adhesion does not vary with the dimensions of the gearing, so that when we reduce the size and increase the speed of the gearing the friction at the journal bearings soon becomes enormous. For light work this is partly obviated by using, instead of metal, some more adhesive material, such as paper, raw hide, &c. But none of these surfaces will stand a pull at all comparable with that on the surface of a locomotive driving wheel.

The most promising methods would appear to be those in which the pressure is prevented from acting across the bearings. This idea is carried out to some extent in the well-known V-grooved gearing, but the unavoidable sliding and grinding of the surfaces makes it impossible to obtain a high duty from it. The idea is more fully carried out in the devices of Sellers, Jenkin and others. I do not know that anything has been suggested—I certainly cannot suggest anything—which does not leave, for the purpose under consideration, much to be determined by trial. Knowing well the effect which actual trial is apt to have upon untried devices, I cannot blame an engineer who prefers to let well enough alone, if a fixed speed ratio is all that he cares for. But I cannot help thinking that a usable connection, which left the speed of the motor independent of that of the car, would be a valuable acquisition; and that a probability of obtaining it would amply justify further experiments with methods of gearing.

DISCUSSION.

[The discussion which follows relates both to the above Paper and to Mr. Leonard's Paper on "Some Objections to Overhead Conductors for Electric Railways," read at the same time, and reported in our last week's issue.]

Mr. ELIAS E. RIES: Mr. Sprague deserves to be congratulated upon the ability and thoroughness with which he has presented the subject, and I take pleasure in adding what little I can to the discussion of such of its features as it seems to me require more elucidation. A matter of considerable importance is whether one or two motors are most advisable for street car work. I myself am in favour of employing but a single motor directly geared to both axles, and it is the universal opinion of electricians and engineers that in a case of this kind a single large unit is better than two or more smaller ones, and this is especially true in regard to street car motors. A great deal has been said about the difficulty of making satisfactory connection with both axles from a single driving source, but this can be overcome, and I may say I have devised a method of doing this which avoids most of the difficulties heretofore encountered. It is a question to my mind whether Mr. Sprague's assertion that independently-driven axles necessarily give better track adhesion can be sustained; in fact, it seems to me that the reverse is generally the case. There can be no doubt, as Mr. Sprague states, that independently driven axles will slip until they get the best grip, but it is also known that a slipping wheel, or pair of wheels, will readily continue doing so under the influence of the acquired impetus and the rotative strain exerted upon them by the motor. However, in ordinary street cars the load is constantly shifting from the forward to the rear axle, and *vice versâ*, due to the lurching of the car and unequal distribution of the weight or load. Therefore, supposing a car to be slightly overcrowded at its rear end, the forward wheels must necessarily slip, and the motor driving them will run light for the time being, leaving the rear motor, which was designed to do but half the total work, to do it all, and subjecting it to an enormous electrical and mechanical strain. I have given this subject considerable attention, and have come to the conclusion that for street cars of ordinary construction the axles should *not* be independently driven, but should be directly connected with each other, preferably through the armature shaft of the motor itself, whose weight is equally borne by both axles. One thing that struck me as very peculiar in connection with the Richmond road, was that an electrical engineer of Mr. Sprague's ability and experience should so utterly abandon all measure of precaution for the safety of his passengers and the public at large as would seem to be indicated by his employment of the track rails and ground as one side of the circuit instead of using a

* Paper read before the American Institute of Electrical Engineers.

Digitized by Google

double overhead conductor. This is the more to be wondered at when it is shown by Mr. Sprague's own description of the elaborate and extensive means employed for connecting the track rails and reinforcing them by separate wires to insure perfect connection with one another, and with the ground pipes, &c., that aside from its danger, this plan is considerably more expensive than a second overhead wire and double trolleys would be. I can only explain this action on the part of Mr. Sprague by asuming that he has found the track return necessary to enable him to ascend the steep grades of the Richmond road by reason of the increased tractive adhesion obtainable, due to the passage of the propelling current from the wheels into the rails. If my memory serves me rightly, it was not very long ago—in his address before the American Street Railway Association at their Philadelphia convention last October—that Mr. Sprague stated that on roads having grades of more than 6 per cent. he proposed to attach a hill horse to the motor car. Whether he intended this as a parting tribute to the usefulness of the patient and long-suffering car horse who has so faithfully served the public I do not know; but at all events, he stated that he did not believe it possible for a self-propelled car to get up the hill in any other way. This was some time after I had announced the results of some experiments I had made,* both with the electric current and electro-magnetism, in which I was able to show and demonstrate that the tractive adhesion of driving wheels could be very largely increased by these means, sufficient, in fact, to enable a motor car to ascend a grade much steeper than any yet surmounted. I may say that we are at present engaged in applying this system to an ordinary steam locomotive, on a prominent railroad, and if the results obtained prove to be anywhere near what we have reason to expect from certain experiments made on a smaller scale, I shall hope to be able to show you a very decided increase in its pulling capacity, and to effect a considerable saving in the cost of operating the road.

Mr. F. J. SPRAGUE: I am rather glad that some argument has come up in the discussion of the Paper. We use in Richmond a double commutator machine, which is unknown to-day to anyone except those whom I have taught. Its plan of winding has never been published or described. It is, as I say, unknown except by the *employés* of my company, and if there is any question as to the similarity of that winding to some other I have not the slightest objection to giving the necessary diagram of connections. It is a series machine, but a series machine which has some peculiar characteristics. It is wound with three sets of coils, and the peculiarity very largely consists in the methods of connecting and certain switches, by which the coils in these machines are commutated and reversed, their field magnetisation and their current varied at will, through progressive changes, by means of which, when desirable, we are enabled under various loads to maintain an almost absolutely constant field, while the current may vary 300 per cent. That has never been done with a motor before; that is, to so regulate the field that, with a variation of 300 per cent., a perfectly constant field will be maintained. This field connection is somewhat peculiar, so much so that it would be useless for me to attempt to describe it now, although I shall take occasiou to publish a description of it in the near future. There are, however, some characteristics of motors other than the mere winding of the armatures or fields, or their regulation, which are essential for street car purposes. It is, as Mr. Mailloux says, a question partly of proportioning, partly of calculation, a putting together of those things which you have at hand to meet those conditions under which you have got to work. Two years ago, I think I may fairly say, such a problem as equipping the Richmond-road, with its abnormal conditions, with the circumstances of manufacture which we had to meet, and in the time that was given to us in the undeveloped state of this art, would have been looked upon as something preposterous. I am frank to confess that had I known what I had to go through, I would, perhaps, have had neither the necessary courage, time nor patience, or have cared to have risked the money which I did. I have spent in Richmond $150,000, and I have learned something. While I do not care to state all I learned, I have taken advantage of it in our future work. A great many of the principles of regulation that have been associated with my name are not characteristic of the Richmond machines. They are designed for other purposes. Now, referring to Mr. Leonard's Paper, a great many of the deficiencies he speaks of exist in Richmond, and unless the machine were of superhuman design, they must exist there. A year ago those machines were put in in a great hurry; the maximum normal capacity that they ought to run at is about seven and a half horse-power. Very frequently they have been called upon to develop ten or eleven horse-power, an increase of about 50 per cent. In the nine months during which this road has been in actual operation, and it has run nearly half a million of miles and carried millions of passengers, not one working car has ever been inside of a closed shed. They have been "housed" in the street. They have run without covers of any kind or character. They have run with six inches of water in the street and brake-beams running in the water, which was splashing on the motors. They have run until you could not tell what the machine was; until the accumulation of mud and oil and filth was of such a character that no other piece of machinery in the world would ever have run. I am not responsible, unfortunately, for the management of the Richmond railway. If so, we would not have the possibility of a number of cars lying in the car shed, so called, unfit for duty, after having been left in the streets during ten days of rain. The report from one of my own inspectors less than one week ago was that there was no more trouble in running a 40-car road by electricity than in one operating three or four cars. He is a level-headed, practical, cautious man, not given to strong statements, and very conservative in what he says or does. Within the next thirty days or so we will have that machine out, and we will put one of those armatures that people have laughed about inside a barrel of water for twenty-four hours, and we will take it out and we will run it.

* See *The Electrician*, Nov. 4, 1887, p. 537.

The breaking of a trolley wire, sometimes caused by a trolley catching in it, can be, of course, almost entirely obviated by one or two precautions; one of these is the non-use of solder in the erection of a line. In putting up the Richmond line we used hard-drawn copper. Hard-drawn copper as it comes out of the mill has a remarkable tenacity, but when it has been handled, and when under the heat of a soldering iron it has been warmed up, you reduce it practically to the strength of soft-drawn copper; so that you will have at the point where solder has been applied a weak spot which entirely nullifies all your other precautions. In our future work this trouble will be entirely removed, because we will not use solder from one end of the line to the other. The use of silicon-bronze or aluminium-bronze drawn for high conductivity and great tenacity will likewise render less possible any accident due to the breaking of the wire. This wire can be drawn of from 100,000 to 150,000 pounds tensile strength to the square inch, and, being put up without solder, I can see little possibility of that wire ever coming down.

So far as the use of poles is concerned, I believe I said in my recent Paper that the objection to overhead wires was entirely reasonable, because people did not put money enough into them. On a new road, where I can make my own conditions before the contract is signed, I am willing to put in just as expensive a road as is desired. Instead of putting in wooden poles in Boston we are putting in iron poles tested up to 1,400 pounds. Instead of setting them in clay we set them in concrete. Those poles will not come down. So far as the span wires are concerned there is no danger of their breaking. As to the use of a single overhead line, that, I know, is a much discussed question. But I find the practice of most people is a single overhead line.

A criticism has been made about the use of two machines on a car. I have spent half an hour trying to get the length of this room with one motor on a 6 per cent. grade, under a condition which happened to give a slimy surface on the rail, and I have seen under the same conditions, on a 10 per cent. grade, on a worse track, two motors handle the heaviest loads. It is not merely because the wheels can get a better grip—you have got your total weight available for traction. The forward wheels can also in case of emergency travel faster than the rear wheels. That has been done, even on a level, and has the advantage of breaking up whatever obstructions there are on the track, and leaving the track perfectly clear. If you put between your wheel a broom or brush you have excellent traction. It could not be done by gearing both wheels to the same motor, simply because you could not get that independence of grip that is necessary. Running both pairs of axles requires certain devices, the use of which, in view of existing street car practice in the matter of constructing running gear, I do not think is advisable. There are some 40,000 or 50,000 cars in the United States, and there are one or two settled principles in them; one is, perfectly independent action of the axles. No four wheels on a car are of the same diameter; they are never cast absolutely alike; they do not run necessarily on the same tread. Any difference in the level of the streets will send the weight of a car down on one side. In fact, it seems to me, in the face of all I have seen, almost trivial to make any objection to the independent driving of the two axles. I admit it is cheaper to build one machine to put on a car, but you can build two smaller machines of the same capacity. Space in a street car is a matter of considerable importance. You want to get large power on a car to handle heavy loads, but you have got to have it in comparatively small space.

As to keeping a trolley on a wire, I am quite willing to enter into a contract to put a trolley on a car which never can come off the wire, and, in fact, some of our cars are now running with one man, and have to run with one man, simply because the railroad people will not pay an additional conductor.

The methods of getting rid of troubles have been, of course, subjects of a great deal of study. It was not possible a couple of years ago to look forward and face all the conditions that arise in practice. We electricians did not know enough about street car practice, and street car men did not know enough about electric railways, so we had to join hands with the street car men, and we had to put the cars and motors into the hands of ignorant men, and meet those difficulties in order to know how to get over them. I think I may safely say that the road we put in sixty days from now will bear about as little resemblance in details to the Richmond road as it is possible for any two roads to bear to each other, simply because of great improvements, not only in the motors, but in the gearing, switches, trolley work, and all overhead superstructure.

A two-wire system requires from two to four times the weight overhead. Where we put a main conductor alongside of the street and reduce the trolley wire to a single one, a fifth of an inch in diameter, that enables us to keep our structure in position a good deal better. So far as safety is concerned, the fact that a horse was killed in Richmond in the early days of running is no criterion of it. Two wires are more liable to come down than one; but you will not get killed with 400 or 500 volts. I have several times taken that potential myself. We do not know whether the horse that was killed in Richmond broke his neck or was killed by electricity. He was boiled in order to get his skeleton; he did have a broken neck; it is not known whether that killed him.

As far as the use of the storage battery is concerned, I am just as anxious as anybody else that the storage battery should be a success. But it will never get on a car in Richmond when they have got to put 4,000 pounds weight on that car. They never will take 20,000 pounds weight up a ten per cent. grade with a storage battery until it is in a good deal higher state efficiency than it is to-day. We have, although not prominently connected with storage battery work, been experimenting for a long time. We keep a car on tap. We have had hundreds of plates built in the past year, trying to devise some means of overcoming the difficulties that exist in

Digitized by Google

storage batteries. We hope to have a normal capacity of discharge in, say, a 35-pound cell of not less than 75 or 80 amperes, and that they can stand 150. The resistance ought to be about one-third or one-fourth of the present storage battery. The plates will be practically indestructible; and, finally, it will not be a Faure cell. That is the sort of thing I am looking for. I no not know whether we will get it. The results, so far, have been very encouraging, but we never will attempt to climb a 10 per cent. grade with it, and we never will put it on the market until we know it is satisfactory. We will do our own experimental work. We expect to get the battery down so that not more than 1,800 pounds is necessary to handle the car under ordinary conditions. I think by the time the Boston road is running, which will be in about five or six weeks, if Providence is not against us in the matter of the weather, we shall be able to show such improvement in the overhead line, as to its efficiency, economy, and appearance, the character of the motors and the work which they will do, as will be a subject for mutual congratulation.

Mr LYNE: There are one or two remarks made by Mr. Leonard that I would like to refer to. The devices, so far as I have been able to discover, in transmitting the power from the motor to the shaft of the car or axle of the car, have been in many cases obsolete devices. For instance, the grooved friction wheel has been used on the "Ben Franklin" that was tried on the Ninth-avenue road. That device was condemned by engineers years ago, because the friction wheel caused flat places. If a sufficient pressure was not brought to bear on these wheels to bring it up to the maximum point at once, the surfaces would slip on one another, and the grooves would have a flat place. When the Fontaine locomotive came out we were led to believe that the whole railroad system of the country would be revolutionised in a few months by that engine. A certain few predicted its utter failure, and it failed, principally in consequence of the tyres getting flat places on them. As soon as they did get a flat place they began pounding themselves to pieces, and the result was a dismantling of the whole affair. We know that the same occurs in locomotives in climbing grades. They slip, get flat places, and then the wheels have to be turned off, or the tyres rather.

Mr. SPRAGUE: The question of depreciation of line is a question of construction very largely. It is certainly not a question of wear. A consideration of the actual time in which a wire is in contact will show this. With cars that are making two minutes headway and running seven miles an hour, with a round trolley wheel, making contact on a round wire, we have almost a line contact, but call it an eighth of an inch contact. Any portion of the wire is in actual contact with the wheel less than one two hundred thousandth-part of the time; in other words, in continuous current contact, not over one hour in twenty-six years. Consequently, the current ought not to rapidly wear the wire out, and it does not. In fact, the period in which any particular part of the wire is in contact is not over one two-thousandth part of a second when the car is moving seven miles per hour.

The question of insulation, leakage, and lightning came up a little while ago. It is a remarkable fact that lightning does not necessarily follow always the single overhead wire. We have had in Richmond quite a number of cases of the line being struck by lightning. Our ground circuit is made by three paths; two through the boilers and water connections, and a third by a covered wire running about 1,000ft. on poles out, and directly down, to the track. We have had lightning come over that wire several times, and the statement of the engineers is that it is about an even thing whether it comes in on that line or the other one. It terminates in a well. So far as the leakage is concerned on that line it can easily be reduced to an average of one-tenth or one-hundredth part of one per cent. It has never been sufficient to cause the slightest interferenc with the operation of the wire except in the case of the short circuit. If existing, it can very easily be perceived by taking the reading of the ampere meter. The leakage is nothing so far as loss of power is concerned.

Mr. D. E. LAIN: About the only part of the matter I wish to speak of now is the means of coupling the motor to the axle. In Mr. Sprague's excellent Paper he compares the method of direct coupling with the others, coupling by means of chain gear, friction gear, &c., in a way which, I think, was rather hard on the direct coupling. I have had some experience with some of these ways, and it seems to me that the method of direct coupling offers certain advantages which no other method offers. The easy motion and perfect noiselessness of the coupling certainly place it ahead of any other means. The simplicity, of course, in this method, is greater than in any other. All the details are reduced to a minimum. The objection, of course, is that on account of the slow speed at which the armature must necessarily run—running no faster than the driving-wheel—a larger machine is necessary. This may be an objection, and may not. In street railway work, where certainly not more than ten horse-power is required, where the whole equipment should not weigh more than, say, 5,000lb. when the car is loaded, the weight of the motor enters as a part of the whole weight; with the weight of a direct coupled motor, that is not of such great importance after all. If the drivers be reduced to, say, 18in., or thereabouts, a motor can be built that is not necessarily over 25 per cent. greater in weight than one using gearing. This small difference is due, in part, at any rate, to the greater efficiency of direct coupling over the gear. Of course, gear transmission is not possible where speed is reduced or changed from, say, one to twelve or one to ten without some considerable loss of power. All this is saved in the direct connection, where the loss by transmission should not be more than a very few per cent. I think before the close of a year, at least before the close of next year, results will be obtained with direct coupling that will show it is possible to use a direct coupled motor even for such small work as street car work, that is quite as efficient, taking it all the way through, and taking the total efficiency of the system, as gearing.

Mr. SPRAGUE: I would like to make one remark in regard to lightning. We had the line struck by lightning several times, and we have had motors on cars burnt out, but I believe I may safely say now that we have got lightning pretty well harnessed. I believe now there is no difficulty whatsoever in absolutely and perfectly guarding a car or a central station, so that lightning simply cannot get to the machine. We have had the lightning come in and ground through the switch at the time the motor men were running the car. They paid not the slightest attention to it. They simply heard the click—that was the end of it. It will now be perfectly guarded against. It cannot get into our machines, and it cannot get into our stations; at least, if it does, it is only one time in 10,000, and then it goes to earth harmlessly.

THE ELECTRICAL AND ALLIED TRADES' SECTION OF THE LONDON CHAMBER OF COMMERCE.

At a meeting of the Committee held on Monday afternoon last it was first resolved that the presence of the reporters at that particular sitting be sanctioned. Sir DANIEL COOPER moved a resolution to the effect that in the case of firms and companies elected to the Committee they should be required to nominate the individual by whom they would be represented. The resolution was not carried; but it was arranged that the Secretary should request the companies concerned to state by whom they would be represented on the Committee. The report of the scrutineers of the election was then received, and letters declining the nomination were read from Sir James Anderson, Messrs. Alabaster and Gatehouse, and Mr. Quintin Hogg. The Committee proceeded to fill the vacancies so created and to decide the ties which had occurred in the ballotting, the result being that the Committee has been finally constituted as follows:—

COMMITTEE.

Telegraph Companies (5).

SIR J. PENDER.
MR. J. H. TRITTON.
THE MARQUIS OF TWEEDDALE.
MR. C. W. EARLE.
MR. R. K. GRAY.

Electrical Manufacturers and Contractors (13).

MR. R. E. CROMPTON.
MR. ALEX. SIEMENS.
MR. M. IMMISCH.
MR. E. GARCKE.
MESSRS. WOODHOUSE AND RAWSON (*Represented by* Mr. F. L. Rawson).
MESSRS. JOHNSON AND PHILLIPS (*Represented by* Mr. B. Pell).
MESSRS. LAING, WHARTON AND DOWN (*Represented by* Mr. C. J. Wharton).
MESSRS. CALLENDER AND SONS. (*Represented by* Mr. W. O. Callender).
MESSRS. DRAKE AND GORHAM (*Represented by* Mr. Drake).
SIR DANIEL COOPER.
MESSRS. W. T. GOOLDEN AND CO. (*Represented by* Mr. W. T. Goolden).
EDISON AND SWAN UNITED ELECTRIC LIGHT COMPANY (*Represented by* Major Flood-Page).
MESSRS. VERITY BROTHERS.

Telephone Companies (3).

MR. J. BRAND.
COL. R. R. JACKSON.
ORIENTAL TELEPHONE COMPANY (*Represented by* Mr. Grewing).

Electricity Supply Companies (6).

MAJOR-GENERAL WEBBER.
THE EARL OF CRAWFORD.
MR. J. E. H. GORDON.
MR. R. WALLACE.
MR. M. PARKER.
MR. R. S. ERSKINE.

Consulting Electrical Engineers (4).

MR. W. H. PREECE.
MR. G. KAPP.
MR. H. SHIRLEY PRICE.
MR. W. H. SNELL.

General (2).

SIR D. SALOMONS.
MR. HEAPHY.

Mr. Crompton was then unanimously elected as Chairman of the Section, and on a ballot being taken the Earl of Crawford and Major Flood-Page were elected vice-chairmen.

It was resolved that the meetings of the committee should be held on the first Monday in each month at 3 p.m. Some other business having been transacted, the committee adjourned.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

15,017. F. KENDALL. Towcester. An improved electrical indicator to show from which room or station a bell has been rung in domestic electric bell and telephone circuits. October 19, 1888.

15,030. J. GWYNNE and C. F. COOPER. London. Improvements in combined steam engines and dynamo-electric machines. October 19, 1888.

15,104. T. A. GARRETT and W. LUCAS. London Improvements in electric meters. October 20, 1888.

15,105. H. F. W. LEWIS, H. A. C. SAUNDERS, and A. C. BROWN. London. Improvements in fire-alarm telegraphs. October 20, 1888.

15,129. J. H. S. BRADLEY and J. H. WILSON. London. Maritime warfare, named or designated the "Automatic Electric Messenger," being an improvement in torpedoes, consisting of two horizontal thin tempered flexible steel fins to give greater stability and an increase of speed. October 20, 1888.

15,130. J. H. S. BRADLEY and J. H. WILSON. London. Maritime warfare, named or designated the "Automatic Electric Messenger," being an improvement in torpedoes, consisting of an automatic diving and floating rudder. October 20, 1888.

15,183. E. EDWARDS. London. Improvements in electrical telegraphs (E. Cassalette and D. Kunhardt, Germany). October 22, 1888.

15,206. A. B. BROWN. Glasgow. Improvements in apparatus for transmitting telegraphic indicating or other analogous signals or movements. October 23, 1888.

15,216. C. M. DORMAN and R. A. SMITH. Manchester. Improvements in the construction of switches for the making and breaking of circuits conveying electric currents. October 23, 1888.

15,237. M. W. W. MACKIE. London. An improved process for the manufacture of alkaline metals, such as aluminum, chromium, &c., by electrolysis and chemical reactions, and apparatus therefor. October 23, 1888.

15,249. S. Z. DE FERRANTI. London. Improvements in dynamo-electrical machines. October 23, 1888.

15,252. O. E. MADDEN and A. F. MADDEN. Improved machines for making battery-plates. October 23, 1888.

15,324. J. C. MARGETSON. London. Improvements in the means for establishing electrical communication in railway trains. October 24, 1888.

15,356. J. HULL. London. Improvements in or applicable to the coating and varnishing machines used in the manufacture of oil-cloth and in calenders and other machines used in analogous processes to prevent the same becoming electrically charged and thus dangerous to combustible materials by giving off sparks. October 25, 1888.

15,369. P. A. FICHET and A. NODON. Improvements in secondary batteries. October 25, 1888.

15,377. R. R. HUTCHINSON. London. Improvements in railways upon which the propulsion of vehicles is effected by means of both electricity and gravity, and apparatus in connection therewith. October 25, 1888.

15,388. A. SHIPPEY. London. Improvements in apparatus for regulating dynamo-electric machines (A. G. Westinghouse, United States). October 25, 1888.

15,395. P. CARDEW. London. Improvements in instruments for measuring and regulating electric currents and differences of potential, partly applicable to telegraphic purposes. October 25, 1888.

15,433. T. J. HANDFORD. London. Improvements in plates or electrodes for secondary batteries, and in the methods of making the same (L. Duncan, United States). October 26, 1888.

15,494. S. ORLOFF. London. Apparatus for operating dynamos by tidal and other like water-power. October 27, 1888.

15,508. L. Q. BRIN and A. BRIN. London Improved methods of producing aluminium and its alloys by means of electricity. October 29, 1888.

15,530. R. W. PAUL. London. Improvements in electrical indicators. October 29, 1888.

15,550. J. SACK. London. Improvements in apparatus for telephonic communication. October 29, 1888.

15,601. C. J. HARCOURT. London. Improvements in the manufacture of electric bell-push fittings. October 30, 1888.

15,612. J. C. LOVE. London. Improvements in insulators for electrical conductors. October 30, 1888.

15,626. P. SCHOOP. London. Improvements in electric batteries. October 30, 1888.

15,648. W. B. CLEVELAND. London. Improvements in electric switches. October 30, 1888.

COMPANIES' MEETINGS & REPORTS.

West India and Panama Telegraph Company (Limited).

Report of the Directors for the half year ended 30th June, 1888, to be submitted to the twenty-third ordinary general meeting to be held at Winchester House, 50, Old Broad-street, London, E.C., on Wednesday, the 14th inst., at 12 o'clock :—

1. The amount to credit of revenue is £49,965. 2s. 0d., and the expenses have been £27,578. 5s. 3d., leaving a balance of £22,386. 16s. 9d., which, with the balance of £1,606 2s. 9d. brought forward from last account, makes a total of £23,992. 19s. 6d. Of this sum the Directors have placed £2,000 to reserve, leaving an available balance of £21,992. 19s. 6d., with which it is proposed to deal as follows :—Payment of 12s. per share on account of arrears of dividend on the First Preference shares £20.737 16s 0d. ; balance to current half year's account £1,255. 3s. 6d. ; total, £21,992. 19s. 6d.

2. The traffic receipts for the six months show an increase of £2,010. 7s. 9d., as compared with the corresponding period.

3. The expenses for repairs to cables are £2,241 in excess of those for the corresponding half-year, owing to an increased number of repairs having been executed, and to the laying in of a greater length of new cable, for the purpose of strengthening the communications.

4. The Company's ss. "Grappler" arrived in the Thames in May last, and, after being docked and repaired, returned to St. Thomas's with 258 knots of new cable for stock.

Australasian Electric Light, Power and Storage Company (Limited).

Report of the Directors to be submitted to the shareholders at the sixth ordinary meeting of the Company, to be held at the offices of the Company, 41, Coleman-street, E.C., on Monday, the 12th inst., at 3 p.m.

Shareholders will note that as these accounts, being up to the end of last year, cover only two months under the new system of expenses, they do not show the advantages reaped from that arrangement, which was adopted at the general meeting held in October, 1887.

Since the date of last report, the efforts of the Board have been largely directed to obtaining and executing the contract for the lighting of the Melbourne Centennial Exhibition, and in conjunction therewith a sale of the plant so to be used. In both of these objects they have been entirely successful.

Having a considerable quantity of suitable stock on hand on the spot, and the advantage afforded by the factory of the Melbourne affiliated company, the contract was obtained by this company on terms which will leave, according to the general manager's report, a very satisfactory profit to both companies. The original and main contract is in the form of a sale, with further arrangements for the erection and working of the plant, amounting in all to about £34,640; but since this first contract further arrangements have been made which add considerably to the magnitude of the installation, and this latter contract is of the nature of hire with option of purchase. The following extract from the official report of the commissioners shows the satisfactory manner in which the contract has been carried out by the company. They say:—"Referring to the lighting of the building by means of the electric light, the Executive has great pleasure in stating that, after a month's trial of what is stated to be the largest single installation in the history of electric lighting ever attempted by a single company, it has proved a marked success."

It is needless to add that every advantage is being taken of this exceptional position to profit by it as a means of extending the ordinary selling business of the Company, and the General Manager anticipates a very marked increase in the sales.

In the report issued in February, 1887, allusion was made to the satisfactory extension that was being given to the operations of the Melbourne Company's lighting station. Unfortunately, the local directors of that company failed to obtain sufficient support financially to keep pace with these developments. In these circumstances an offer was made of very substantial assistance from this Company. At this juncture, however, a foreign firm of electrical engineers offered to supply plant on very easy terms of payment, and, acting under this inducement, the local company adopted for their extension the foreign system. From these circumstances many misunderstandings and difficulties have arisen, which have seriously crippled the Melbourne Company, whose local shareholders have now insisted upon a reconstruction, the precise details of which have not yet been received here.

At the same time preliminary arrangements have been made in Melbourne for raising a considerable capital by local capitalists for the development of electric lighting on a large scale. There have been certain negotiations with this group, but at the present moment the directors are not in a position to make any statement with regard to them. In the meantime, it is very evident that a great development of electricity in all its branches is just commencing in the Colonies, and that very remunerative work is to be had for a company strong enough to undertake it.

An arrangement has been made with Messrs Gibbs, Bright and Co., Melbourne, who have consented to act as consulting agents to this Company, and it is believed that this will prove of great benefit in future transactions.

Major Flood-Page has unfortunately been obliged, by stress of his other occupations, to retire from the Board, but continues to assist the Company with his advice when consulted. The Directors retiring by rotation at this meeting are Messrs. Van Tromp and Sanderson, who, being eligible, offer themselves for re-election.

The auditors, Messrs. Deloitte, Dever and Co., also retire, and are eligible for re-election.

NEW COMPANIES REGISTERED.

CROMPTON AND CO. (LIMITED).—This company has been formed to acquire the business, freehold premises, plant, stock, and goodwill of R. E. Crompton and Co., electric light engineers, Chelmsford and London. The capital is £140,000, in shares of £5 each, consisting of 20,000 7 per cent. preference shares and 8,000 ordinary shares, and the present issue is of the preference shares, about half of which, it is stated, have already been privately subscribed by the directors and their friends. Messrs. Crompton and Co. have, from the beginning of the electric light movement, taken a prominent part in the manufacture and installation of lighting plant, and have established a reputation for satisfactory work. It is stated that the business has grown considerably during the last few years, and that the orders now on hand, together with those in negotiation, are of such magnitude as to make it a matter of necessity that additional capital should be provided. It is in order to enable this capital to be subscribed under the protection of limited liability that the undertaking has been converted into a public company. The books of the firm have been examined by Messrs. Duncan Bryce and Co., chartered accountants, who certify that the profit for the five and three-quarter years ended March 31, 1888, has amounted to £40,029, being an average of £6,969 per annum, and that the balance-sheet for the last nine months of that period shows a net profit of £8,912. Since this certificate was prepared it has been ascertained that the amounts therein set aside to provide for bad and doubtful debts and completion of work in hand were not sufficient. The consequence is to reduce the profit for the last nine months; but the effect of this on the average profits for the six years is, it is stated, immaterial.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended November 2nd, 1888, amounted to £4,949.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of October was 4,210, estimated to produce £3,300, against 3,417 messages, producing £3,024, in the corresponding month of last year. The traffic receipts for the month of July, estimated at £3,100, realised £3,086.

DIRECT SPANISH TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the month of October, 1888, amount to £2,210, against £2,276 in the corresponding period of last year, a decrease of £66.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this company for the month of October, 1888, amounted to £55,742, and to £53,089 in the corresponding period of 1887, an increase of £2,653.

EASTERN EXTENSION, AUSTRALASIA AND CHINA TELEGRAPH COMPANY.—The traffic receipts of this company for the month of October, 1888, amounted to £38,660, against £40,018 in the corresponding period of 1887, a decrease of £1,358.

EASTERN AND SOUTH AFRICAN TELEGRAPH COMPANY.—In our advertisement columns will be found a notice that on the 16th inst. 260 First Mortgage Debentures will be drawn for payment on Jan. 1, 1889.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic receipts of this company for October amounted to £23,600, and for the period from 1st January to 31st October to £226,200. For the corresponding months of 1886 and 1887 they amounted to £217,800 and £220,880 respectively.

MEXICAN TELEGRAPH CABLE COMPANY.—This company has just declared a quarterly dividend of 2½ per cent., being the usual rate.

SOUTH OF ENGLAND TELEPHONE COMPANY (LIMITED).—The directors of this company at their meeting on Thursday last, declared a dividend of 6 per cent. per annum on the preference shares of the company for the half-year ended 31st October.

SUBMARINE CABLES TRUST.—The balance of 10s. on the coupons of the Submarine Cables Trust, due last April, will, it is announced, be paid on the 15th inst. Further particulars will be found in our advertisement columns.

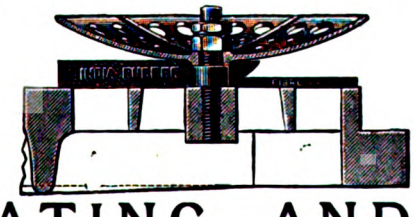
WEST COAST OF AMERICA TELEGRAPH COMPANY.—The traffic receipts of this company for the month ended October 31st, 1888, amounted to £6,600.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended November 2nd, 1888, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £4,110.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The traffic receipts for the half month ended October 31th, 1888, were £2,715, as compared with £2,803 in the corresponding period of 1887, a decrease of £33.

NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature. Suitable for any shaped guards. Only one quality manufactured.

"12, John-street, Sunderland, 26th Sept., 1885.

"DEAR SIRS,—In reply to your letter of the 25th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue to get them from you as required.—Yours faithfully, JAMES WESTOLL."

For further Testimony and Prices, apply to MOSSES & MITCHELL, 68-71, Chiswell Street, London.

No. 548.—Vol. XXII. FRIDAY, NOVEMBER 16, 1888. Price 4d.

NOTES.

Our New York correspondent telegraphs under date November 13th as follows:—"United States Supreme Court reverses decision of lower Court, Massachusetts, and holds that Government can bring suit there to invalidate Bell. Decision upsets every point raised in Bell demurrer, but involves no direct electrical issue."

It hardly need be said that this is a decision of the highest importance. Those who have followed the course of events in connection with the endless litigation on the Bell patents will remember that in the Circuit Court at Boston some months ago a decision was given in the action brought by the Attorney-General on behalf of the United States Government, in which it was alleged that the Bell patents were obtained by fraud, and that the specification contained particulars taken from the patent of Elisha Gray, whose application was at the same time in the possession of the Patent Office, and leave was therefore applied for to cancel the patents. The Boston Court held, however, that in the absence of any specific statute they had no power to grant leave to cancel a patent. The Court further expressed an opinion that the allegations raised against the validity of the patent would, if sustained, form a ground of defence in any suit brought by the Bell Company for infringement, and that this fact debarred the Attorney-General from proceeding. This decision was immediately appealed against, and we now learn from our correspondent's telegram that the Supreme Court has wholly upset the judgment of the Court below. Thus it would seem that the whole question of the priority of invention of the telephone is again thrown open. Whatever the final result may be it is a matter of great regret that allegations of the character in question should find any place in the history of one of the most beautiful and useful adaptations of electrical science.

A financial paper "understands that the promoters of the scheme for laying a cable across the Pacific from Vancouver to Australia have arranged for a public meeting to be held at Cannon street Hotel on the 21st of this month, in order to bring their undertaking more prominently under public notice. They propose to get up a deputation to wait upon Lord Salisbury to induce him to take an interest in the undertaking, and to order the expedition of the survey of the bottom of the Pacific which the Admiralty have been engaged upon for some time.'

It is interesting to contrast this appeal to Government with the action of the Eastern and South African Company, which is about to lay lines on the West Coast of Africa. On her way to the Cape of Good Hope the cable ship "Amber" took 380 soundings between Bonny and Cape Town, over a zig-zag course of 3,377 miles. The total distance in a direct line would be 1,624 miles, which, if divided by the number of soundings obtained, would represent one sounding to every 4¼ miles. The aggregate number of fathoms of sounding wire run out was 212,065, and the wire lost 2,526, or about one per cent. On her way northward the same vessel will take a second line of over 100 soundings, extending over 1,100 miles.

Mr. Harold P. Brown (in a letter which will be found in our correspondence columns) "trusts that we will modify our opinion on the dog-killing experiments." In our issue of October 5 (page 691) we expressed the opinion that Mr. Brown's experiments "had conclusively proved that an alternating current is fatal *to a dog* at a very much lower potential than a continuous current." We really do not see our way at present to "modify" this opinion, nor do we quite understand in what direction Mr. Brown wishes a modification to be made. If, however, Mr. Brown is asking us to admit that he has demonstrated that the use of alternate currents of 200 volts and upwards ought to be interdicted, then we must decline to allow that he has said or done anything which leads to such a conclusion. Against Mr. Brown's experiments on dogs, and his vivid picture of the terrible condition of overhead wiring in the States, we set the fact that 35,000 lamps in London are already wired in overhead circuits carrying 2,400 volts, and that not a single accident has hitherto resulted. It is true that nearly two years since, a lad, who had no business to touch the wire at all, tried to cut the line with a pair of pliers, and fell through a skylight and was killed, but an occurrence of this kind cannot fairly be charged against the system itself. Moreover, as we have before stated, several *employés* of the company in question have received shocks of the full potential of 2,400 volts without serious result. What does our correspondent make of these facts? We may add, in conclusion, that Mr. Brown undoubtedly deserves credit for calling attention to the dangerous condition of the New York high-tension circuits, and what he has really done is to enforce the lesson that the design and construction of such lines must be brought to the highest possible state of perfection.

The simple fact that the filament of an incandescent lamp continues to glow a brief interval after the cessation of the

Digitized by Google

current, has been seized upon by not a few ill-instructed enthusiasts who have proposed to increase the available output of current generators by distributing the current momentarily between a number of separate circuits. This is evidently one of those ideas from which the Patent Office is entitled to expect a permanent source of revenue. A patent has recently been granted to T. A. Edison, in which identically the same *modus operandi* is employed, with the view, however, not of increasing the available energy, but of distributing what may be called the virtual potential between several different circuits. The object is, in fact, to secure a system of high-tension distribution with continuous currents. Mr. Edison appears to have discovered that an incandescent lamp of, say, 100 volts, when subjected, at intervals of a second, to an E.M.F. of 500 volts for periods of one-fifth of a second, will give the same light as it would under a continuous E.M.F. of 100 volts. This was perhaps to be expected; but it would be interesting to know whether the life of the lamp does not suffer. Mr. Edison proposes to employ this method for the distribution of high-tension electricity, and its utilisation in lamps or motors designed for currents of lower voltage. The high-tension current is to be taken either to local centres or to the house of the consumer, and is there to be placed on a distributing commutator, driven by an electric motor, by which it will be placed on a number of separate circuits each for the required interval of time. So far as our present information extends, we must confess that we entirely fail to see the advantage of the plan. There is no real transformation of potential, and even if the difficulty of sparking at the commutator be overcome, the necessity for employing an electric motor in every circuit is a most serious drawback; in fact, if it were not associated with the name of Edison we should not have thought the proposal worth attending to. We wonder, by-the-bye, what has become of Edison's motor-generator central station at Llewellyn Park.

It is understood that the Metropolitan Electric Supply Company have given the Westinghouse Company a contract for the equipment of a central station adapted for 3,000 lamps in Sardinia-street, Lincoln's-inn-fields. Some regret has been expressed that the company should have adopted plant of foreign manufacture, but we believe it will be found that additional orders will be placed in English hands, and it is also to be remembered that the Westinghouse Company own a considerable number of patents taken out by English inventors. At the same time it is easy to understand that this renewed American invasion is not exactly welcomed in many quarters.

The Kensington Court (Draft) License, of which we published the full text last week, raises an issue of considerable importance, and upon which the terms of the license appear to be inconsistent if not contradictory. The question is as to the degree of responsibility attaching to the undertaker in respect of the lamps, fittings and wiring of the consumers' premises. Clause 13, under the head of Regulations as to Supply, says:—

"The undertakers shall not be in any way responsible for any defects in the construction of any electric lines or fittings within such premises . . . . where such electric lines or fittings have not been supplied by them, nor for any neglect in the maintenance of any such electric lines or fittings where they do not belong to the undertakers or are not under their control."

And yet under "Regulations as to Safety," Clause 1, we read:—

"The electricity shall be delivered to the poles on the consumers' premises in some manner free from risk of causing fire on the premises in question, whether such fire should or might be . . . . partly due to any defective action of the lamps, motors, storage cells, conducting wires, or other fittings connected with the poles for the purpose of using the supply of electricity."

It is clear that one or other of these clauses must be remodelled; and we think there can be no question that the *intention* of the Board of Trade, whilst providing for all reasonable safeguards, is to free the undertaker from responsibility for the consumers' fittings. The whole question is to be discussed at a meeting of the Committee of the Electrical Trades Section, to be held this (Friday) afternoon, when it is probable that an attempt will be made to frame a model set of regulations on the lines laid down by the Board of Trade, but which, with suitable modifications, might be adapted for central lighting stations on any system.

Lord Armstrong's rejoinder in this month's *Nineteenth Century* on what he calls "The Cry for Useless Knowledge" has certainly the merit of putting in clear terms the irreconcilable divergence of views which are entertained on the subject of technical instruction. Sir Lyon Playfair, the spokesman of the Technical Association, is an advocate for including within the scope of technical education the teaching of specific trades and industries. "I, on the contrary," says Lord Armstrong, "hold that workshops and factories, or other places where actual business is carried on, are the proper schools for the learning of such trades and industries." It is well to have no illusions on a matter of this importance; and from actual experiment at his own works and with his own workpeople, Lord Armstrong draws the conclusion that, neither from economic considerations nor from consideration of advantage to the workmen *as a body*, is "a knowledge of the sciences and arts which lie at the basis of all industries"—the ideal of Sir L. Playfair—either profitable or attainable.

Sir L. Playfair's contention that the workmen "desired to dignify and fructify their labour by understanding it" is easily demolished by proofs that they (again *as a body*) have no such aspirations. For our part we believe Sir Lyon would admit these proofs if pressed a little harder, and would then shift his ground to one which savours more of polities than of economics. What he really desires is that the workman shall be made to dignify, and so forth, whether he likes it or no. A similar desire, with its inevitable complement, has been caricatured in America. "Every citizen shall be free to do what he darned pleases; and if he doesn't we'll make him." There is something to be said, no doubt, for compulsory technical instruction, as for compulsory education in general. But Lord Armstrong does well to remind us that national decadence cannot be averted by academic remedies of this description.

THE township of Allendale is apparently prepared to pin its faith to Mr. R. P. MILBURN and his "new patent electric light."

"The interesting proceedings" (says the *Hexham Courant*) "were witnessed by a large number of people, and general satisfaction was expressed with the result of the trial. Lights of 10 and 27 candle-power were produced, the effect of which was in every respect highly satisfactory, whilst general surprise was evinced at the simplicity of the apparatus for the generating and storing of the electricity. Subsequently, a meeting of the committee was held in the Church Sunday School Room, Mr. M. Stephenson presiding. Mr. Milburn gave particulars regarding his electric light and the method of applying it to the town. As to the cost of maintenance, he stated that it would cost *about ½d. an hour for twelve lights* such as they would require. . . . The process would be this: They would make a battery to last thirty hours; the electricity would be generated from the primary battery, passed into the secondary or accumulators, and from thence to the lamps. . . . As to the first cost, he could not just then say anything definite, but as soon as he had ascertained what the pottery manufacturers would make these special batteries for—made of earthenware—he would draw up an estimate and forward it to them. . . . Assuming that it took six cells to drive 12 lamps, anyone desiring to have the light brought into their private dwellings could have it by adding another cell. To obtain the light by water or motive power would cost a great deal more than by his system, the dynamo alone probably costing £150. His system of a chemical battery was on the same principle as the paraffin lamps, but instead of paraffin oil they poured chemicals in, and having connected the wires they obtain the lights. Mr. Milburn further remarked that there were only two chemical batteries at the present time—one a German patent, and the other his own, so that really the thing was quite in its infancy. Mr. Walton: If we go in for this light I suppose we will be the first town in the kingdom that will have done so.—Mr. Milburn: Yes."

That the "chemical battery on the principle of the paraffin lamp is *quite* in its infancy," and that Allendale will really be the very first place in which an electric light of 10 candle-power has been maintained at a cost of one twenty-fourth of a penny per lamp-hour, are propositions of which Mr. MILBURN may be left in undisputed ownership; and we should advise Allendale not to deprive him of them at any price.

The Trinidad-Demerara Cable.—We learn that the cable between Trinidad and Demerara is now repaired.

Wath-on-Dearne.—Messrs. Charles Stanley and Son, who have recently erected extensive additions to their South Yorkshire Oil and Soap Works, have had the latter department lighted throughout with electric light.

A Corner in Zinc.—The *Cote Libre* mentions a Belgian-German combination to take charge of zinc on the lines of the Copper Syndicate. The principal producers of the Rhine district will take part in the movement.

The Cox-Walker-Swinton Magneto Electric Bells.—The Royal Cornwall Polytechnic Society have awarded the Equitable Telephone Association a prize medal for the exhibit of the above at the recent Falmouth Exhibition.

"The Elementary Principles of Electric Lighting."—A new and revised edition is now in the press of "The Elementary Principles of Electric Lighting," by A. A. Campbell Swinton, and will shortly be published by Messrs. Crosby Lockwood and Co. The first edition is out of print.

Bournemouth.—At a meeting of the Improvement Commissioners, last week, a letter was read from Mr. St. Aubin Angrove, of London, asking them to sanction an application to the Local Government Board for permission to lay down electric tramways from the eastern district of Bournemouth to the Arcade, and from Poole to the top of Commercial-road, West Bournemouth. The commissioners thought tramways connecting the outlying districts with the town desirable, but opposed their being laid down in the town proper.

Eastern Telegraph Company (Limited).—This company have called a meeting of shareholders to authorise the issue of 20,000 new shares of £10 each for the purpose of enabling the company to subscribe and pay for a like number of shares of the Eastern and South African Telegraph Company (Limited). The latter company is about to lay a line of cables along the southern part of the West Coast of Africa, from the Cape to Loanda, where it will join the existing lines, forming an important alternative route to the Cape; and while adding greatly to the security of the service will, in the opinion of the directors, yield satisfactory results to the Eastern Company.

An International Telephonic System.—At the last International Telegraph Congress telephonic questions were practically ignored. We learn, however, that at the forthcoming meeting of the Congress at Paris, there is to be a special telephone section. One of the main objects of this section will be to formulate a large scheme of international telephony, whose ramifications will embrace Paris, Berlin, Vienna, Brussels, Rome, and Amsterdam, and, according to our authority, London also. Of course, the first step towards the practical realisation of the scheme must be the adoption of a uniform telephone tariff and system of regulations.

The Gulcher Company.—We are informed that the Gülcher Company have secured the contract for lighting Messrs. W. and J. Players' new rolling mill, Spring Hill, Birmingham. Six 2,000 candle-power Gülcher arc lamps will be used for lighting the mill, and the dynamo and engine are being put in large enough for 10 lamps, in case it is necessary to extend the mill, in which case the balance of power will be used for running incandescent lamps. The Gülcher Company have also just completed the lighting of the Sunderland Co-operative Stores with three Gülcher arc lamps and incandescent lamps. A 3,000 candle-power lamp is placed on a bracket in front of the building for lighting the street.

Kensington.—The question of the lighting of the parish of Kensington by electricity came up at the Kensington Vestry meeting yesterday.—Mr. Lindsay objected to mapping out the parish, as was proposed, to four companies, and said the committee pretended not to want to grant a monopoly, but that would be virtually created by the adoption of their proposal. He therefore proposed that the vestry should give authority to the whole seven companies that had applied for permission to supply light, without allotting any particular part of the area. Mr. Lindsay's proposal was carried by 38 to 19.—Messrs. Jordan (chairman), Duffield, and Wilson resigned their position on the committee in consequence of this decision.—Ultimately the vestry reconsidered their decision, and postponed the matter for a fortnight.

Bristol.—At a recent meeting of the Bristol Sanitary Authority the chairman stated that a committee had been appointed by the Council to consider the question of electric light. They had already had an offer from a gentleman who had succeeded in placing the electric light in Bath and Taunton. They gave him the cost of gas throughout the main streets which it was suggested should be lighted in Bristol, and pointed out to him that the committee would probably agree to adopt the electric light if it could be done at the same cost as the gas. He (the chairman) did not think that at present it could be

Digitized by Google

done at the same cost; but the system had been adopted in other towns, and he thought the time was arriving when it should receive their consideration. What he wished to point out was that the matter had not been lost sight of.

The London Chamber of Commerce.—Electrical and Allied Trades Section.—The following circular has been issued to the members of the section:—"Dear Sir: The committee of the above section, which has just elected Mr. R. E. Crompton for its chairman, and the Earl of Crawford and Major Flood Page for its vice-chairmen, are desirous of proceeding to the discussion of questions primarily affecting the trade. With this object they wish to take the opinion of the members of the section at large as to which are, in their opinion, the topics most pressing for immediate consideration. I shall be glad, therefore, if you will kindly send me, at your early convenience, or in any case not later than the 18th instant, a list of such questions as you would suggest should be brought under the notice of the committee, inscribing them in the order of the importance which you may attach to them.—Yours faithfully, KENRIC B. MURRAY, Secretary."

Supposed Death from Electricity.—"A man, aged forty-six, is supposed," says the *Lancet*, "to have met his death on Saturday last from an electric shock when following his employment at the Consett Iron Company's works, county Durham. It appears that the supply of light was interfered with owing to the wind fraying the gutta-percha covering of the wires, and to get at the defect he had to cross along a slippery plank leading from the top of the boilers. The general impression is that by not wearing the gloves provided for such occasions he had received a shock from the uncovered wires; at all events, he was found on the ground with a wound on the back of his head. Life was not then extinct. He was removed to the County Infirmary, and died in about two hours. Strange to say, in a case like this, where medical evidence might have been useful, if not essential, to determine the real cause of death, the coroner did not call any, notwithstanding the remark of one of the jury that 'there certainly ought to have been a doctor here.'"

Improvements in Secondary Battery Plates.—A correspondent writes us as follows:—"In the *Electrical World* of October 27 a new secondary battery of M. Faure's is described. This invention seems likely to revolutionise secondary battery construction, since M. Faure substitutes the work of the individual molecule for that of the concrete plate. There is a striking resemblance between M. Faure's latest device and that of M. Bandsept (see *The Electrician*, 4th May, 1888), who completely solved the question from the point of view of molecular work. M. Bandsept, it will be remembered, made his electrodes of finely divided material, which was compressed into plates while played upon by a fine spray of some liquid suitable for the end in view. The chemical reaction is consequently more thorough and more powerful. Looking at the question from this aspect, there can be no doubt as to the great importance of work like that of M. Faure. In virtue of mechanical laws, this scientific solution of the problem ought to give tangible and good results."

Fire at Messrs. Willans and Robinson's.—A destructive fire occurred at the Thames Ditton premises of Messrs. Willans and Robinson early on yesterday morning, resulting in the complete destruction of the machine shops, the smithy, and the foundry. We understand that the firm had in hand at the time of the fire upwards of one hundred engines for electric lighting purposes; but that the system of construction pursued at these workshops—the parts of the engines being independently constructed to guage and template—will enable the firm to replace their stores from outside sources, and so complete their contracts without serious delay. The erecting shop in which there were many engines in course of erection were saved. Only a few dynamos were destroyed, as many of the engines on the premises were waiting dynamos which had not yet arrived. All drawings, books, and papers were rescued, and a large stock of castings remained uninjured. Steps have already been taken to replace the machinery, and the firm have received many prompt and kind offers of assistance from other firms with whom they do business.

Barnet.—At a recent meeting of the Barnet Local Board the Lighting Committee reported that the electric lighting contractor (Mr. Joel) had been in communication with them on the subject of the complaints made in regard to the lighting, and had stated that he had every reason to believe that everything would be in proper working order by the 20th inst. The committee had inspected a 32 candle-power lamp; and the contractor had undertaken that all the lamps should be worked to a similar standard, with the addition of reflectors and improved appliances. The report having been received, Mr. James said that, taking into account the time that had elapsed since the first attempt to light the town by electricity, he thought the Board should take some decisive action. They had had a good many promises, but none of them had been carried out. He proposed that notice should be given to the contractor to terminate his contract, expressing the opinion that by so acting the Board could not be accused of undue haste or want of consideration. Mr. Samuels pleaded for the contractor, saying that he considered the Board would do a very unwise thing if they gave the notice. He moved, as an amendment, that the recommendation of the Lighting Committee as to the notice be not acted upon; and this was adopted.

The Lighting of Mr. Alfred C. de Rothschild's Town House. Messrs. E. T. Mackrill and Co., of Aylesbury, have just completed a fine installation at Mr. Alfred C. de Rothschild's house in Seamore-place. The engines and dynamos are situated in the stables some 250 yards away from the house, the current being taken to the lights by means of 37/12 insulated cables, laid under the roadway in 5-inch iron pipes. The generating plant consists of two 9 horse-power (nominal) Otto gas engines, which drive direct, through 6-inch belting, two shunt-wound dynamos having each an output of 145 volts and 65 amperes. These machines supply current to 165 E.P.S. accumulators, arranged in three parallels of 55 each; the cells are of the 31 L 1888 pattern, with a capacity of 600 ampere-hours. The station is provided with the usual charging, discharging, and distributing switches, as well as ammeters, voltmeters, and resistance coils. In addition to supplying current for the lights, the cells are used to drive a small E.P.S. motor actuating a Blackman air propeller, and also to start the gas engines, the dynamos being momentarily converted into motors. The lights, some 300 in number, are mostly of 20 candle-power. Every group is arranged throughout in two sections, and the artistic possibilities of the electric light are everywhere made the most of. Cockburn's fuses, it may be added, are used wherever necessary. This is, we believe, the first private undertaking which has been allowed to run cables under the roads.

Electric Lighting Activity.—As an instance of the activity now prevalent in electric lighting circles, we give the following list of installations upon which Messrs. B. Verity and Sons are either at work or have quite recently completed:—An installation of 800 lights for the Earl of Rosebery's house at Mentmore; an installation on board the steam yacht "Eros," for Baron Arthur de Rothschild, of Paris; an installation of 500 lights, similar to the Earl of Rosebery's, for Sir John Dixon

Digitized by Google

Poynder; an installation of 3,000 lights, Willans' engines and Siemens' dynamos, is being commenced at the Savoy Mansions. Besides these works Messrs. Verity and Sons have at the present time upwards of 35 smaller installations or wiring works in progress, including the Earl of Dysart, per General Webber; Sir David Salomons, Bart.; the Royal College of Surgeons; rewiring of the Isthmian Club, Piccadilly; also Sir William M'Cormack's house; wiring for 1,200 lights for Lord Walsingham's chambers in Piccadilly, Mr. Peter Robinson's private house, Mr. D'Oyly Carte's private house, Mr. Mather's (of Messrs. Mather and Platt), and Dr. Lennox Browne's. Another work just completed is the complete re-wiring of the Junior United Service Club, about 340 lights; the whole of this work, including the manufacture of new electroliers and fittings throughout the place, was completed in three weeks. Messrs. Verity and Sons are also making the principal electroliers for the Glasgow Municipal Buildings, and have recently completed some fittings for Her Majesty's yachts "Victoria and Albert" and the "Osborne." In addition to the above, the Holloway College has been fitted with 340 additional lights, and the Avenue Theatre with 600 lights.

Ipswich.—"'The Council are of opinion that facilities for obtaining electric light and power should be afforded to the inhabitants of Ipswich.' The Corporation, in making this statement," says the *East Anglian Daily Times*, "accurately represented the opinion of the inhabitants. Authorities and people are agreed, and an electric lighting company is ready to go ahead, but the terrible red-tapeist comes in the way. Messrs. Laurence, Paris and Scott, more or less connected with whom in the enterprise are believed to be the great firms of Fowler of Leeds and Ransomes of Ipswich, applied to the Corporation for power to make two little tunnels, about a foot square, along each side of Tavern-street, next the pavement, with the object of running their electric cables along them, and supplying the houses on either side. The tunnels would simply occupy a narrow space along the channels of the street, and very little trouble could arise from their construction. The Corporation were willing that the cables should be laid, but before granting the authority decided to take counsel's opinion. A very simple thing it seems, granting a company permission to lay a cable along a street, but counsel, on being applied to, declared the proposal fraught with danger. All sorts of technical and legal difficulties might arise. We are not the master of our own streets, though we think we are. Counsel averred that it would be dangerous to grant the proposed permission, and recommended that the electric lighting engineers be compelled to obtain a Provisional Order. When the Provisional Order is obtained the engineers are masters, not the town. We cannot give permission; it must be taken from us by application to an official in London. Some obscure clerk there, after the necessary rigmarole has been gone through, can grant Messrs. Laurence, Paris and Scott the power which the Corporation of Ipswich dare not give them. They will then be as it were above the Corporation—independent of them, with absolute rights over the little subways. Fine fun for somebody who draws a salary to give these permits, but not a very sensible thing for a modern town. In the second place, to obtain a Provisional Order will cause a great delay. The electric engineers must lose the winter, all salaries and establishment expenses running on for an extra twelve months, greatly increasing the ultimate cost of the electric light. There will be the expense also of the Provisional Order, and such luxuries are not to be had for nothing. The more the light costs the promoters and manufacturers, the more they must charge the public." These remarks of the *East Anglian Daily Times* are for the most part of a decidedly sensible character.

Birmingham.—At the meeting of the Town Council on Friday last, Alderman Pollock moved "That the consideration of the notice given on behalf of Messrs. Chamberlain and Hookham of their intention to apply to the Board of Trade, under the provisions of the Electric Lighting Acts, for a provisional order empowering them to supply electricity for public and private purposes within this borough, be deferred; and that it be an instruction to the General Purposes Committee to inquire into the whole question of the supply of electricity, and to report to this Council thereon, and particularly as to the advisability or otherwise of the Corporation, as the local authority, themselves acquiring the power to supply electricity within this borough." There seemed to be an erroneous impression abroad, namely, that after the committee declined to give their consent to the provisional order, the matter must be deferred for another year. That, however, was not so. It was not necessary that the consent should be obtained before February. An important matter for consideration was whether the Corporation themselves would apply for a provisional order, as they were very reluctant that anyone should interfere with the management of the streets. At the same time the resolution ought not to be regarded as being hostile to the introduction of the electric light; on the contrary, he thought there was a strong feeling that some steps should be taken in that direction, but the Council would have to see not only what was good for the promoters, but for the public. They must also take care that if electricity were supplied it should be supplied on reasonable terms. If the General Purposes Committee should recommend that the Council should apply for a provisional order, then it was certain that there would be a delay of twelve months, because they could not apply before next November. In 1882 a report was presented by the Gas Committee recommending the Council not to interfere in the matter of the supply of electricity, but to enable others to do so. He had received that morning a letter from Messrs. Chamberlain and Hookham's solicitors, stating that their clients offered at any time within two years to sell their undertaking, works, and plant to the Corporation at actual cost price. This offer enabled the Corporation, if they wished, to postpone their final decision, but afforded the best guarantee that the promoters' outlay would be judicious and honest.—Alderman Johnson, as chairman of the General Purposes Committee, seconded the motion, and echoed the sentiments of Alderman Pollack that the committee had but one desire, that the experiment should be tried, and that it should be tried after due consideration of the question as to whether the Corporation should undertake it or whether they should grant a license to an outside applicant.—Alderman White said it seemed to him that the time had come when the Council should take up the question of electric lighting. He believed that the Council did right a few years ago in deferring the subject; but the time had now arrived when they might reconsider it, and they should also bear in mind the proposal of Messrs. Chamberlain and Hookham to sell the undertaking to them if they desired. He thought that was a guarantee of good faith.—Mr. Fallows pointed out that electric lighting was very extensively carried on in America, so that it could no longer be regarded as an experiment.—Mr. Osler hoped the committee would not approach the subject with any prejudice in favour of gas, but with a desire to give every facility for the development of electric lighting in Birmingham. Knowing something about the difficulties of electric lighting, he trusted the Corporation would not undertake it if they could get an adequate guarantee that they would keep perfect control of the streets.—Alderman Pollack, in reply, said the committee would take care to report before February on the subject.

NOTES ON ELECTRO-MAGNETIC INDUCTION.

BY DR. J. A. FLEMING, M.A.

(Continued from page 7.)

Elementary Theory of the Induction Coil.—Aiming rather at the elucidation of principles than very copious treatment, we shall consider the problem of the induction coil in its simplest form. Let there be two bobbins of wire in suitable positions for producing mutual induction and without iron cores. Let the constant inductance of the first or primary be denoted by L and its ohmic resistance R, and the similar quantities for the second or secondary coil be N and S, and let M be the co-efficient of mutual inductance.*

Let there be a source of constant electromotive force, E, which can be applied or withdrawn from the primary circuit. We denote by x the strength of the current in the primary at any time t after closing the primary circuit by applying the battery to it. Also we denote by y the current in the secondary circuit at any time reckoned from the same zero.

If, then, at any instant the currents are x and y, the following state of things exists in the circuits.

The electromotive force E is the impressed force on the primary circuit.

The effective electromotive force producing the current x is Rx, the counter-electromotive force of self-induction is $-L\frac{dx}{dt}$, the counter-electromotive force of mutual induction due to the current y at that instant in the secondary circuit is $-M\frac{dy}{dt}$, and hence the relation which at any instant holds good between these quantities is

$$L\frac{dx}{dt}+M\frac{dy}{dt}+Rx=E,$$

which is an expression of the fact that the external electromotive force balances the internal electromotive forces, and the effective electromotive force driving the current.

Similarly, for the secondary circuit we have an induced electromotive force due to the induction of the primary on the secondary equal to $M\frac{dx}{dt}$ and a counter-electromotive force of self-induction $N\frac{dy}{dt}$; hence

$$N\frac{dy}{dt}+M\frac{dx}{dt}+Sy=0,$$

since there is no external impressed electromotive force. The complete solution of the problem of finding the currents x and y at any instant is obtained by the solution of these simultaneous differential equations—

$$L\frac{dy}{dt}+M\frac{dy}{dt}+Rx=E,$$

$$N\frac{dy}{dt}+M\frac{dx}{dt}+Sy=0.$$

As our object is not specially to deal with difficulties of analysis we shall simplify the problem by supposing that the two circuits are similar in every respect. This makes $R=S$ and $L=N$, and the equations become

$$L\frac{dx}{dt}+M\frac{dy}{dt}+Rx=E \quad . \quad . \quad . \quad . \quad \text{(i.)}$$

$$L\frac{dy}{dt}+M\frac{dx}{dt}+Ry=0 \quad . \quad . \quad . \quad . \quad \text{(ii.)}$$

Bearing in mind that L is in ordinary parlance the "number of lines of force" which are linked with the primary circuit due to unit current in its own circuit, and that M signifies the number of lines of force which are common to both, or linked in with both circuits, when unit current flows in each, we see that M can never be greater than L, but that under all circumstances we must have

$$M < \text{or} = L,$$

also $$M < \text{or} = N;$$

hence $$M^2 < \text{or} = LN,$$

or $LN - M^2$ always a positive quantity, and the maximum value which the co-efficient of mutual inductance M can have is $\sqrt{LN}$, or the square root of the product of the self-inductances.

In order to separate the differentials in (i.) and (ii.) we differentiate each equation with respect to t, and obtain—

$$L\frac{d^2x}{dt^2}+M\frac{d^2y}{dt^2}+R\frac{dx}{dt}=0 \quad . \quad . \quad . \quad \text{(iii.)}$$

$$L\frac{d^2y}{dt^2}+M\frac{d^2x}{dt^2}+R\frac{dy}{dt}=0 \quad . \quad . \quad . \quad \text{(iv.)}$$

Multiply (iii.) by L, (iv.) by $-M$, and (i.) by R, and then, adding the three equations together, we obtain—

$$\frac{d^2x}{dt^2}+\frac{2LR}{L^2-M^2}\frac{dx}{dt}+\frac{R^2}{L^2-M^2}x=\frac{ER}{L^2-M^2} \quad . \quad . \quad \text{(A)}$$

and a similar elimination gives us

$$\frac{d^2y}{dt^2}+\frac{2LR}{L^2-M^2}\frac{dy}{dt}+\frac{R^2}{L^2-M^2}y=0 \quad . \quad . \quad . \quad . \quad \text{(B)}$$

We have now separated the differentials in x and y, and the solution of these equations depends, as is well known,* upon the solution of an auxiliary quadratic equation—

$$m^2+\frac{2RL}{L^2-M^2}m+\frac{R^2}{L^2-M^2}=0,$$

the solution of which is—

$$m=-\frac{R}{L+M}, \text{ or } -\frac{R}{L-M}.$$

Hence the general solution of (A) and (B) is—

$$x=Ae^{-\frac{Rt}{L+M}}+Be^{-\frac{Rt}{L-M}}+\frac{E}{R}, \quad . \quad . \quad . \quad \text{(5)}$$

and

$$y=A'e^{-\frac{Rt}{L+M}}+B'e^{-\frac{Rt}{L-M}} \quad . \quad . \quad . \quad . \quad . \quad \text{(6)}$$

where A, B, A', B' are constants of integration to be determined from the circumstances of the flow. To do this, however, a preliminary discussion is necessary. Let us suppose that the primary current is fully established, and has a steady value I, and hence that MI lines of force penetrate through the secondary circuit. This quantity is then the electro-magnetic momentum of the secondary circuit, because when the current in the primary is steady there is no current in the secondary circuit.

Let us now suppose that the primary circuit is broken, and that the circumstances of the "break" are such that all these MI lines of force are removed at a uniform rate in a small time, δt, from the secondary circuit.

During this time δt an electromotive force will operate upon the secondary circuit equal in magnitude to $-\frac{MI}{\delta t}$, or to the rate of decrease of the included lines of force. We have seen in Chap. II. that when an electromotive force E acts on a circuit of inductance L and resistance R that the current i at any time t after the commencement of the application of the electromotive force is given by the equation

$$i=\frac{E}{R}(1-e^{-\frac{R}{L}t}).$$

Now, in the case considered the inductance and resistance of the secondary circuit are L and R, and the impressed electromotive force applied during a time δt is $\frac{MI}{\delta t}$. Hence, at any time *during* the interval of time δt the value of the secondary current is given by the equation

$$i=\frac{MI}{\delta t R}(1-e^{-\frac{R}{L}t}).$$

* Continental writers often call L and N the potentials of the bobbins on themselves, and M the potential of one bobbin on the other.

* *See* Boole's "Differential Equations," p. 192, 2nd Edition.

Digitized by Google

This gives us the value of the inverse induced current at any time during the breaking of the primary. Expand the above expression by the exponential theorem and it becomes

$$i = \frac{M}{L} I - \frac{M}{L^2} \frac{R \delta t}{1 \cdot 2} + \frac{M}{L^3} \frac{R^2 \delta t^2}{1 \cdot 2 \cdot 3} - \text{etc.}$$

At the instant when the removal of lines of force or the cessation of the induction through the secondary takes place the impressed electromotive force ceases and the secondary current begins to die away. If we suppose the "break" of the primary to be very sudden, δt becomes practically zero, and we have

$$i = \frac{M}{L} I ;$$

that is to say, the secondary current starts with a value equal to $\frac{M}{L}$ of that of the steady primary.

The state of things in the secondary circuit immediately *after* the break of the primary is, then, this: the electromotive impulse due to stoppage of the primary has generated a current of initial value $\frac{M}{L} I$ in the secondary, but there is no impressed electromotive in the secondary circuit. If at any instant after the break the current in the secondary circuit is i, the law of decay of this current is expressed by the equation

$$L \frac{di}{dt} + R i = 0.$$

The solution of this is

$$i = C e^{-\frac{R}{L} t}$$

and the constant C is found from the condition that when $t = 0$ $i = \frac{M}{L} I$. Hence we have

$$i = \frac{M}{L} I e^{-\frac{R}{L} t} \quad \ldots \ldots \quad (7)$$

This gives us the value of the direct or "break"-induced current in the secondary at any instant after the break of the primary. Graphically, this may be represented by a curve, such as that in Fig. 10. During the time O T in which the primary is being broken the induced electromotive force is creating an induced current, the rising strength of which is represented by the rise O P. The time occupied by the break δt is O T. As O T is diminished in value, the magnitude of the maximum ordinate P T, approximates to $\frac{M}{L} I$, and this is the initial value of the inverse secondary current when the break is very sudden. After the break the current decays away along a path represented by P Q, and becomes zero only after an infinite time.

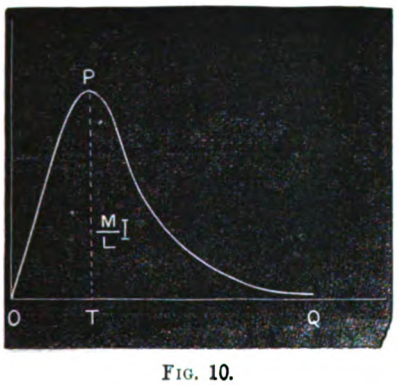

FIG. 10.

The whole quantity of the induced current is obtained by integrating equation (7) with respect to the time from zero to infinity, thus:

$$\int_0^\infty i \, dt = \int_0^\infty \frac{M}{L} I e^{-\frac{R}{L} t} = \frac{M I}{R}.$$

We see, then, that both the maximum value and whole quantity of the direct secondary current are proportional to the coefficient of mutual induction and to the strength of the primary current, and, moreover, that the whole quantity of electricity set in motion in a secondary circuit of total resistance R by suddenly removing from it M I lines of force is equal to the quotient of number of lines removed by the total resistance of the secondary circuit.

If the induced current is sent through a galvanometer the indications are proportional to the magnitude of $\frac{M I}{R}$. If, however, the induced current is employed to magnetise steel needles, the magnetisation acquired is dependent upon the magnitude of $\frac{M I}{L}$, and is therefore greater in proportion as the coefficient of self-induction of the secondary circuit is less. Lord Rayleigh has pointed this out,* and shown by experiment that within certain limits the magnetising effect of the break-induced current on steel needles is *greater* the smaller the number of turns of which the secondary consists, the opposite being, of course, true of the galvanometer. The galvanometer takes account of the induced current as a whole; whilst the magnetising power depends mainly on the magnitude of the current at the first moment of its formation, without regard to the time which it takes to subside.

(To be continued.)

HERTZ'S RESEARCHES ON ELECTRICAL OSCILLATIONS.

BY G. W. DE TUNZELMANN, B.SC.

(Concluded from page 18.)

The latest researches of Dr. Hertz on electrical oscillations of which accounts have been published at present are described in a Paper "On Electro-Dynamic Waves in Air, and their Reflection," in Wiedemann's *Annalen*, Vol. XXXIV., p. 609. The author had been endeavouring to find a more striking and direct proof of the finite velocity of propagation of electro-dynamic waves than those which he had hitherto given, for, though these are quite sufficient to establish the fact, they can only be properly appreciated by one who has obtained a grasp of the results of the entire series of researches.

In many of the experiments which have been described Dr. Hertz had noticed the appearance of sparks at points in the secondary conductor, where it was clear from geometrical considerations that they could not be due to direct action, and it was observed that this occurred chiefly in the neighbourhood of solid obstacles. It was found, moreover, that in most positions of the secondary conductor the feeble sparks produced at a great distance from the primary became considerably stronger in the vicinity of a solid wall, but disappeared with considerable suddenness quite close to the wall. The most obvious explanation of these experiments was that the waves of inductive action were reflected from the wall and interfered with the direct waves, especially as it was found that the phenomena became more distinct when the circumstances were such as to favour reflection to the greatest possible extent. Dr. Hertz therefore determined upon a thorough investigation of the phenomena.

The experiments were made in the Physical Lecture Theatre, which is 15 metres in length, 14 metres in width, and 6 metres in height. Two rows of iron columns, running parallel to the sides of the room, would collectively act almost like a solid wall towards electro-dynamic action, so that the available width of the room was only 8·5 metres. All pendant gas fittings were removed, and the room left empty, with the exception of wooden tables and forms, which would not exert any appreciable disturbing effect. The end wall, from which the waves were to be reflected, was of solid sandstone, with two

* *Phil. Mag.*, Ser. 4, Vol. XXXIX., 1870, p. 429.

Digitized by Google

doors in it, and the numerous gas pipes attached to it gave it, to a certain extent, the character of a conducting surface, and this was increased by fastening to it a sheet of zinc 4 metres high and 2 metres broad, connected by wires to the gas pipes and a neighbouring water pipe. Special care was taken to provide an escape for the electricity at the upper and lower extremities of the zinc plate, where a certain accumulation of electricity was to be expected.

The primary conductor was the same that was employed in the experiments described in my last Paper, and was placed at a distance of 13 metres from the zinc plate, and, therefore, two metres from the wall at the other end of the room. The conducting wire was placed vertically, so that the E.M.F.s to be considered increased and diminished in a vertical direction. The centre of the primary conductor was 2·5 metres above the floor of the room, which left a clear space for the observations above the tables and benches. The point of intersection of the reflecting surface with the perpendicular from the centre of the primary conductor will be called the point of incidence, and the experiments were limited to the neighbourhood of this point, as the investigation of waves striking the wall at a considerable angle would be complicated by the differences in their polarisation. The plane of vibration was therefore parallel to the reflecting surface, and the plane of the waves was perpendicular to it, and passed through the point of incidence.

The secondary conductor consisted of the circle of 35 centimetres radius, which has been already described. It was movable about an axis through its centre perpendicular to its plane, and the axis itself was movable in a horizontal plane about a vertical axis. In most of the experiments the secondary conductor was held

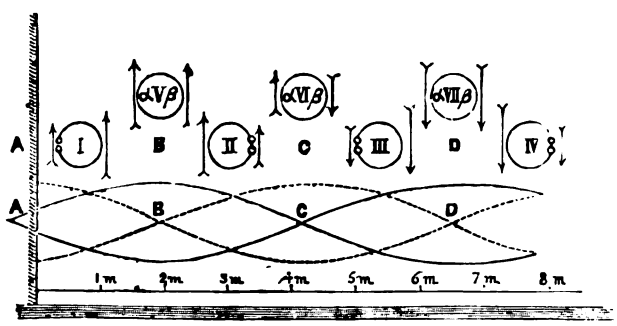

FIG. 12.

in the hand by its insulating wooden support, as this was the most convenient way of bringing it into the various positions required. The results of these experiments, however, had to be checked by observations made with the observer at a greater distance from the secondary, as the neighbourhood of his body exerted a slight influence upon the phenomena. The sparks were distinct enough to be observed at a distance of several metres when the room was darkened, but when the room remained light they were practically invisible even when the observer was quite close to the secondary.

When the centre of the secondary was placed in the line of incidence and with its plane in the plane of vibration, and the air-space was turned first towards the reflecting wall and then away from it, a considerable difference was generally observed in the strength of the sparks in the two positions. At a distance of about 0·8 metre from the wall the sparks were much stronger when the air space was directed towards the wall, and its length could be adjusted so that while there was a steady stream of sparks when in this position, they disappeared entirely when the air space was directed away from the wall. These phenomena were reversed at a distance of 3 metres, and recurred, as in the first case, at a distance of 5·5 metres. At a distance of 8 metres the sparks were stronger when the air space was turned away from the wall, as at the distance of 3 metres, but the difference was not so well marked. When the distance was increased beyond 8 metres no further reversal took place, owing to the increase in the direct effect of the primary oscillation and the complicated distribution of the E.M.F. in its neighbourhood.

The positions I., II., III., and IV. (Fig. 12) of the secondary circle are those in which the sparks were strongest, the distance from the wall being shown by the horizontal scale at the foot. When the secondary circle was in the positions V., VI., and VII., the sparks were equally strong in both positions of the air space, and quite close to the wall the difference between the sparking in the two positions again diminished. Therefore the points A, B, C, D in the diagram may in a certain sense be regarded as nodes. The distance between two of these points must not, however, be taken as the half-wave length, for if all the electrical motions changed their directions on passing through one of these points the phenomena observed in the secondary circuit would be repeated without variation, since the direction of oscillation in the air space is indifferent.

The conclusion to be drawn from the experiments is that in passing any one of these points part of the action is reversed, while another part is not. The experimental results, however, warrant the assumption that twice the distance between two of these points is equal to the half-wave length, and when this assumption is made the phenomena can be fully explained.

For, suppose a wave of E.M.F., with oscillations in a vertical direction, to impinge upon the wall, and to be reflected with only slightly diminished intensity, thus giving rise to stationary waves. If the wall were a perfect conductor, a node would necessarily be formed in its surface, for at the boundary and in the interior of a perfect conductor the E.M.F. must be infinitely small. The wall cannot, however, be considered as a perfect conductor, for it was not metallic throughout, and the portion which was metallic was not of any great extent. The E.M.F. would therefore have a finite value at its surface, and would be in the direction of the impinging waves. The node, which in the case of perfect conductivity would occur at the surface of the wall, would, therefore, actually be situated a little behind it, as shown at A in the diagram. If, then, twice the distance A B —that is to say, the distance A C—is half the wave-length the steady waves will be as represented by the continuous lines in Fig. 12. The E.M.F.s acting on each side of the circles, in the positions I., II., III., and IV., will therefore at a given moment be represented in magnitude and direction by the arrows on each side of them in the diagram. If, therefore, in the neighbourhood of a node the air space is turned towards the node, the strongest E.M.F. in the circle will act under more favourable conditions against a weaker one under less favourable conditions. If, however, the air space is turned away from the node, the stronger E.M.F. acts under less favourable conditions against a weaker one under more favourable conditions. In the latter case the resultant action must be less than in the former, whichever of the two E.M.F.s has the greater effect, which explains the change of sign of the phenomenon at each quarter-wave length.

This explanation is further confirmed by the consideration that if it is the true one the change of sign at the points B and D must take place in quite a different manner from that of the point C. The E.M.F.s, acting on the secondary circle, in the positions V., VI., and VII., are shown by the corresponding arrows, and it is clear that in the positions B and D, if the air space is turned from one side to the other, the vibration will change its direction round the circle, and, therefore, the sparking must during the rotation vanish either once or an uneven number of times. In the position C, however, the direction of vibration remains unaltered, and therefore the sparks must disappear an even number of times, or not at all.

The experiments showed that at B and D the sparking diminished as the air space receded from α, vanished at the highest point, and again attained its original value at the point β. At C, on the other hand, the sparking continued throughout the rotation, being a little stronger at the highest and lowest points. If, then, there is any change of sign in the position C, it must occur with very much smaller displacements than in the other positions, so that in any case there is a distinction such as required between this and the other two cases.

Another very direct proof of the truth of Dr. Hertz's representation of the nature of the waves was obtained. If the secondary circle lies in the plane of the waves instead of in the plane of vibration, the E.M.F. must be equal at all points of the circle, and for a given position of the air space, the sparking must be directly proportional to its intensity. When the experiment was made it was found, as expected, that at all

Digitized by Google

distances the sparking vanished at the highest and lowest points of the circle, and attained a maximum value at the points in the horizontal plane through the point of incidence.

The air space was then placed at such a point and close to the wall and was then moved slowly away from the wall, when it was found that while there was no sparking quite close to the metal plate, it began at a very small distance from it, rapidly increased, reached a maximum at the point B, and then diminished again. At C the sparking again became excessively feeble, and increased as the circle was moved still further away. The sparking continued steadily to increase after this, as the motion of the circle was continued in the same direction, owing, as before, to the direct action of the primary oscillation.

The curves shown by the continuous lines in Fig. 12 were obtained from the results of these experiments, the ordinates representing the intensity of the sparks at the distances represented by the corresponding abscissæ.

The existence in the electrical waves of nodes at A and C, and of loops at B and D, is fully established by the experiments which have been described; but in another sense the points B and D may be regarded as nodes, for they are the nodal points of a stationary wave of magnetic induction which, according to theory, accompanies the electrical wave and lags a quarter wave-length behind it.

This can easily be shown to follow from the experiments, for when the secondary circle is placed in the plane of vibration with the air space at its highest point, there will be no sparking if the E.M.F. is uniform throughout the space occupied by the secondary. This can only take place if the E.M.F. varies from point to point of the circle, and if its integral round the circle differs from zero. This integral is proportional to the number of magnetic lines of force passing backwards and forwards across the circle, and the intensity of the sparks may be considered as giving a measure of the magnetic induction, which is perpendicular to the plane of the circle. Now in this position vigorous sparking was observed close to the wall, diminishing rapidly to zero as the point B was approached, then increasing to a maximum at C, falling to a well-marked minimum at D, and finally increasing continuously as the secondary approached still nearer to the primary. If the intensities of these sparks are taken as ordinates, positive and negative, and the distances from the wall as abscissæ, the curve shown by the dotted lines in Fig. 12 is obtained, which therefore represents the magnetic waves.

The phenomena observed in the first series of experiments described in this Paper may therefore be regarded as due to the resultant electric and magnetic actions. The former changes sign at A and C, the latter at B and D, so that at each of these points one part of the action changes sign, while the other does not, and therefore the resultant action which is their product must change sign at each of these points, as was found to be the case.

When the secondary circle was in the plane of vibration the sparking in the vicinity of the wall was observed to be a maximum on the side towards the wall, and a minimum at the opposite side, and as the circle was turned from one position to the other there was found to be no point at which the sparks disappeared. As the distance from the wall was increased the sparks on the remote side gradually became weaker, and vanished at a distance of 1·08 metre from the wall. When the circle was carried further in the same direction the sparks appeared again on the side remote from the wall, but were always weaker than on the side next to it; the sparking, however, no longer passed from a maximum to a minimum merely, but vanished during the rotation once in the upper and once in the lower half of the circle. The two null points gradually receded from their original coincident positions, until at the point B they occurred at the highest and lowest points of the circle. As the circle was moved further in the same direction, the null points passed over to the side next to the wall, and approached each other again, until when the centre was at a distance of 2·35 metres from the wall the two null points were again coincident. B must be exactly halfway between this point and the similar point previously observed, which gives 1·72 metre as the distance of B from the wall, a result which agrees, within a few centimetres, with that obtained by direct observation. Moving further in the direction of C, the sparking at different points of the circle became more nearly equal, until at C it was exactly so. In this position there was no null point, and as the distance was further increased the phenomena recurred in the same order as before.

Dr. Hertz found that the position of C could be determined within a few centimetres, the determinations of its distance from the wall varying from 4·10 to 4·15 metres; he gives its most probable value as 4·12 metres. The point B could not be observed with any exactness, the direct determinations varying from 6 to 7·5 metres as its distance from the wall. It could, however, be determined indirectly, for the distance between B and C being found to be 2·4 metres, taking this as the true value, A must have been 0·68 metre behind the surface of the wall, and 6·52 metres in front of it. The half-wave length would be 4·8 metres, and by an indirect method it was found to be 4·5 metres, so that the two results agree fairly well. Taking the mean of these as the true value, and the velocity of light as the velocity of propagation, gives as the vibration period of the apparatus 1·55 hundred-millionths of a second, instead of 1·4 hundred-millionths, which was the theoretically calculated value.

A second series of experiments were made with a smaller apparatus, and though the measurements could not be made with as much exactness as those already described, the results showed clearly that the position of the nodes depends only on the dimensions of the conductors and not on the material of the wall.

Dr. Hertz states that after some practice he succeeded in obtaining indications of reflection from each of the walls. He was also able to obtain distinct evidence of reflection from one of the iron columns in the room, and of the existence of electrodynamic shadows on the side of the column remote from the primary.

In the preceding experiments the secondary conductor was always placed between the wall and the primary conductor—that is to say, in a space in which the direct and reflected rays were travelling in opposite directions, and gave rise to stationary waves by their interference.

He next placed the primary conductor between the wall and the secondary, so that the latter was in a space in which the direct and reflected waves were travelling in the same direction. This would necessarily give rise to a resultant wave, the intensity of which would depend on the difference in phase of the two interfering waves. In order to obtain distinct results it was necessary that the two waves should be of approximately equal intensities, and therefore the distance of the primary from the wall had to be small in comparison with the extent of the latter, and also in comparison with its distance from the secondary.

To fulfil these conditions the secondary was placed at a distance of 14 metres from the reflecting wall, and, therefore, about 1 metre from the opposite one, with its plane in the plane of vibration, and its air space directed towards the nearest wall, in order to make the conditions as favourable as possible for the production of sparks. The primary was placed parallel to its former position, and at a perpendicular distance of about 30 centimetres from the centre of the reflecting metallic plate. The sparks observed in the secondary were then very feeble, and the air space was increased until they disappeared. The primary conductor was then gradually moved away from the wall, when isolated sparks were soon observed in the secondary, passing into a continuous stream when the primary was between 1·5 and 2 metres from the wall—that is, at the point B. This might have been supposed to be due to the decrease in the distance between the two conductors, except that as the primary conductor was moved still further from the wall the sparking again diminished, and disappeared when the primary was at the point C. After passing this point the sparking continually increased as the primary approached nearer to the secondary. These experiments were found to be easy to repeat with smaller apparatus, and the results obtained confirmed the former conclusion, that the position of the nodes depends only on the dimensions of the conductor, and not on the material of the reflecting wall.

Dr. Hertz points out that these phenomena, which are exactly analogous to the acoustical experiment of approaching a vibrat-

Digitized by Google

ing tuning-fork to a wall, when the sound is weakened in certain positions and strengthened in others, and also to the optical phenomena illustrated in Lloyd's form of Fresnel's mirror experiments; and as these are accepted as arguments tending to prove that sound and light are due to vibration, his investigations give a strong support to the theory that the propagation of electro-magnetic induction also takes place by means of waves. They, therefore, afford a confirmation of the Faraday-Maxwell theory of electrical action. He points out, however, that Maxwell's, in common with other electrical theories, leads to the conclusion that electricity travels through wires with the velocity of light, a conclusion which his experiments show to be untrue. He states that he intends to make this contradiction between theory and experiment the subject of further investigation.

Section II.—Electro-Magnetic Fields.

(*Continued from page 821, Vol. XXI.*)

135. *Electro-Magnetisation of Annealed Iron Wire.*—In order to observe the magnetisation of a piece of iron when there is practically no demagnetising effect from its own poles, it has been stated that a rod or wire must be selected whose length is at least 300 times its diameter. Now, if the magnetic moment is measured by either of the two methods of Gauss already detailed (para. 125), the iron wire tested must be very small in diameter, as it is not convenient to test a very long wire by these methods. And the strength of pole developed in a wire of small diameter is necessarily very small even when the iron has acquired a high magnetisation, in consequence of

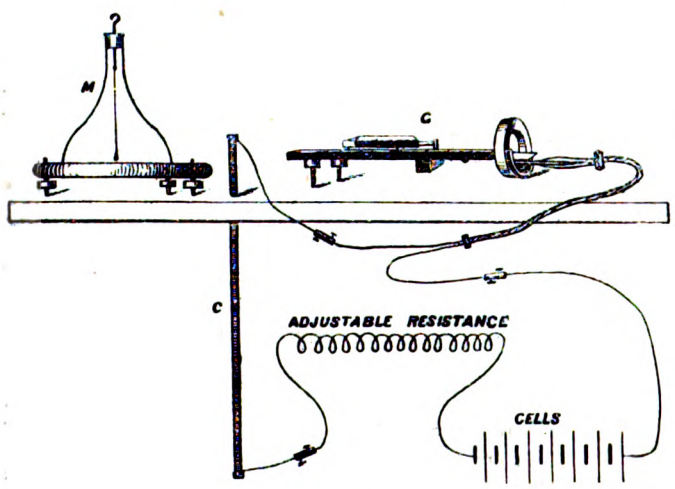

Fig. 116.

which the magnetometer can only be deflected to very small angles. With a light mirror attached to the needle, the amplitude of the deflections can be considerably increased by a ray of light reflected from the mirror on to a screen, and in this manner very small movements of the needle can be accurately observed. We are here, however, employing a magnetometer without a mirror attachment, and it is therefore advisable to arrange matters so that the needle is deflected to a considerable angle, say to 50 deg. or 60 deg., when the iron is near its highest magnetisation. The intermediate deflections can then be read with ease and accuracy. This may be effected conveniently by using a long core and placing it vertically, as shown at C (Fig. 116). As large a diameter as No. 11 B.W.G. iron wire may be used for a core 3ft. long, and yet be over the necessary ratio of length to diameter. This gives sufficient sectional area of iron to develop, at high magnetisations, enough strength of pole to strongly deflect the needle, the top end of the core being within 20 centimetres from the needle. In this diagram, C is the magnetising coil wound round a brass tube, and fixed vertically by passing it through a hole in the table. The iron wire core of the same length as the tube should slip easily into it, and the upper end of the latter be fixed a little above the level of the magnometer needle, in order that the pole, which is formed at a little distance from the end, may act more nearly in a horizontal line with the needle. As the iron becomes more magnetised the poles move up more to the ends, but are always some slight distance off, even when most strongly magnetised. By this method, the upper pole acts powerfully on the needle; and with a long core the action of the lower pole is very feeble. If we neglect the action of the lower pole, the intensity of field at the needle, placed r centimetres away from the upper pole, is

$$\frac{m}{r^2} \text{ C.-G.-S. units,}$$

where m is the strength of pole (*see* paras. 108 and 109). But where accuracy is required the action of the lower pole must be taken into account. Taking the point of p (Fig. 117) as the centre of the magnetometer needle and SN as the magnetised core, it will be seen that the lower pole (R centimetres from p) would repel a unit north pole at p with a force of

$$\frac{m}{R^2} \text{ dynes.}$$

But this force is in an oblique direction, and the needle moving in a horizontal plane is only influenced by horizontal forces. It is therefore only the horizontal component of the above force that we have to deal with. Resolving by the parallelogram of forces we have by similar triangles

$$\text{horizontal component} : \frac{m}{R^2} :: r : R,$$

whence the horizontal force $= \frac{m\,r}{R^3}$ dynes.

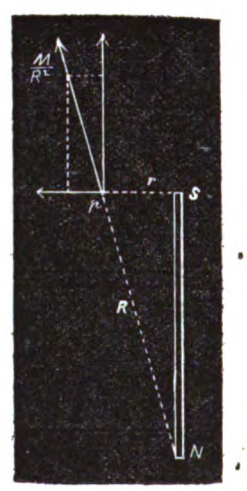

Fig. 117.

The resultant force f at the needle is then the difference between the forces due to each pole, viz.:—

$$\frac{m}{r^2} - \frac{m\,r}{R^3} \text{ dynes.}$$

Now, the force in dynes on unit pole at a point is the same thing as the intensity of field at that point, and, therefore, the above value of f represents the strength of field at the needle centre due to both poles of the core. This field also acts on the needle at right angles to the earth's horizontal field H, and, therefore (by para. 119)

$$f = H \tan \alpha,$$

where α is the angular deflection of needle. Glancing at the figure it will be noticed that the end of the magnetometer needle is viewed, the earth's meridian being supposed to be at right angles to the plane of the paper, and the magnetising coil C being placed east or west of the needle.

Digitized by Google

Equating the above values of f, and reducing by simple algebra, we have

$$m = \frac{H \tan \alpha r^2}{1 - \left(\frac{r}{R}\right)^3},$$

which gives the strength of each pole in C.-G.-S. units, and from which the magnetisation may be calculated by

$$I = \frac{m}{a} \text{ C.-G.-S. units,}$$

where a is the sectional area of the core in square centimetres.

The cubed fraction in the denominator is the ratio of the distances of the poles of the core from the needle, and this fraction is small when the core is long and placed near to the needle. If the cube of this fraction is very small and is neglected it will be seen that the formula represents the action of the upper pole alone.

The manner of taking the test is precisely the same as that already detailed for the short iron rod. In the figure the adjustable resistance is shown conventionally, the practical apparatus having already been detailed in para. 131 and Fig. 112. The following practical example may serve as a guide to work by:—A brass tube of three millimetres bore and 90 centimetres long was first served round with an insulating covering of brown paper and then wrapped round carefully with No. 18 silk-covered copper wire. This took 657 turns of wire in all, or 7·3 turns per centimetre. The current was obtained from a maximum number of 12 secondary cells through two adjustable resistances, one of German silver wire (Fig. 112) and the other of water, the latter being for the smaller alterations in resistance. Measurements of the current strength were taken on a Thomson-graded galvanometer G (Fig. 116), the manner of using which has been described. The controlling magnet was not used in any of the readings, and therefore the current was found by

$$C = \cdot 18 \frac{D}{P} \text{ amperes,}$$

where D is the deflection and P the position of the needle-box (para. 132). A curve was then plotted on squared paper from the readings in the same manner as described for the last curve, the vertical ordinates being magnetometer deflections and the horizontal ordinates the magnetising forces, calculated in ampere-turns *per foot*. The reason of this is that the last curve (Fig. 115) was plotted from readings taken with a magnetising coil one foot long, and therefore the magnetising forces in ampere-turns expressed on that curve are actually ampere-turns *per foot*. Now we wish to compare the rates of magnetisation of the two cores under test for a given series of magnetising forces, and therefore to be able to compare the two curves together we plot the magnetising forces exerted on the core at present under consideration in the same units as those employed on the previous core (para. 134), viz., ampere-turns per foot. We have already noted (para. 130) that the magnetising fore in C.-G.-S. units is equivalent to

$$\frac{\text{ampere-turns}}{\text{length of coil (centimetres)}} \times 1{\cdot}257;$$

that is, the number of ampere-turns per centimetre multiplied by 1·257, from which it may be noticed that magnetising forces are proportional to the number of current-turns per unit of length. When comparing two or more coils of *the same length* the strength of field set up by them or their magnetising forces are proportional simply to their respective number of ampere-turns, but when dealing with coils of different lengths the simple statement of the number of ampere-turns on each offers no basis of comparison between them; we must know the number of ampere-turns for a certain definite length of coil in each. (We are referring to cylindrically-wound coils, as generally used for electro-magnets, not ring-shape coils, as in galvanometers.) For example, take two coils, each wound with one layer of wire of similar size and around bobbins of similar diameter; one bobbin being twice the length of the other. If the same current is passed through both, the number of ampere-turns in the former is twice that in the latter, and the length of wire wound on is also twice as much, but the magnetic field developed by each, or their respective magnetising forces, are equal, for we have the same number of ampere-turns per unit of length in each. Again, take two coils, each wound with one layer of wire of similar size and around bobbins of similar length; one bobbin being twice the diameter of the other. If the same current is passed through both, the number of ampere-turns per unit of length is the same in each, and therefore the magnetic field developed by each is the same, although the length of wire wound on the former is twice that on the latter. And, further, if we take two exactly similar bobbins and wind any size wire on each, the magnetic fields developed are proportional to the number of ampere-turns on each; and if the current is the same in both, the fields are proportional simply to the number of turns or to the length of wire wound on each. The remarks in para. 128 allude to this latter and more simple case.

(To be continued.)

MEETINGS OF SCIENTIFIC SOCIETIES, &c.

(To-night) FRIDAY, November 16th.

INSTITUTION OF CIVIL ENGINEERS.

7:30 p.m. Students' Meeting. Paper to be read, "Experiments on Beams." By Mr. ED. C. DE SEGUNDO, C.E.

TUESDAY, November 20th.

ROYAL VICTORIA HALL.

8:30 p.m. Lecture, "The Throat and Voice." By Mr. W. D. HALLIBURTON, M.D., D.Sc.

INSTITUTION OF CIVIL ENGINEERS.

8 p.m. Ordinary Meeting. Discussion on Mr. BEAUMONT'S Paper on "Friction-Brake Dynamometers."

WEDNESDAY, November 21st.

ROYAL METEOROLOGICAL SOCIETY.

7 p.m. Ordinary Meeting at the Institution of Civil Engineers. Papers will be read on "Results of an Investigation of the Phenomena of English Thunderstorms during the Years 1857-59." By Mr. G. J. SYMONS, F.R.S. "Notes on the Meeting of the International Meteorological Committee at Zurich in September, 1888." By ROBERT H. SCOTT, M.A., F.R.S.

SOCIETY OF ARTS.

8 p.m. First Meeting of the 150th Session of the Society. Opening Address by the Duke of ABERCORN, C.B., Chairman of the Council.

THURSDAY, November 22nd.

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

8 p.m. Ordinary General Meeting. "On a System of Electrical Distribution." By Mr. HENRY EDMUNDS, Member.

SATURDAY, November 24th.

PHYSICAL SOCIETY.

3 p.m. "On the Measurement of the Luminosity of Coloured Surfaces." By Capt. ABNEY, R.E., F.R.S.

"On the Suppressed Dimensions of Physical Quantities." By Prof. RÜCKER, F.R.S.

The Electric Telegraph Association of Victoria.—The third annual meeting of the Victorian Electric Telegraph Association took place in Melbourne in the first week of September, there being a large attendance. The committee, in presenting their annual report to the members of the association, expressed their regret that notwithstanding their strenuous exertions to improve the position of operations by securing a modification of the grading system adopted by the Public Service Board, they had not succeeded, but good work had been done with regard to many other matters. The members present accorded a unanimous and hearty vote of thanks to the retiring committee for their efforts to improve the position of operators. The election of officers and committee was then proceeded with, and resulted as follows:—President, Mr. H. A. Krone; vice-president, Mr. H. J. Allan; secretary, Mr. Joseph Tatchell; treasurer, Mr. M. H. Fitzgerald; committee, Messrs. F. Peacock, William Taylor, F. J. Edgar, T. Howard, J. R. Jackson and J. K. Brown.

Brussels.—The installation at the Théâtre de la Monnaie is to be enlarged, and accumulators are to be put in at the Maison du Roi. These accumulators, like those at the Théâtre de la Monnaie, will be charged from the central station at Laeken.

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny.
Editorial, Publishing and Printing Offices:

No. 1, SALISBURY COURT, FLEET STREET, LONDON, E.C.

Telephone No. 2714.

All Communications to be addressed to "The Electrician," 1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to "The Electrician."

All letters intended for insertion in "The Electrician," or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.

"The Electrician" is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.

"The Electrician" is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.

SPECIAL NOTICE.

Owing to the increase in the number of pages of "The Electrician," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.	6 months.	12 months.
	s. d.	s. d.	s. d.
For Foreign Parts and Colonies:— Within Postal Union	6 6	12 6	24 0
„ Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	14 6	28 0

The rates for the United Kingdom remain as follows:— 5 0 ... 10 0 ... 19 6

TO ADVERTISERS.

"The Electrician" offers exceptional advantages to Advertisers. **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

Trade Advertisements *intended for the current issue must be handed in not later than First Post on Thursday morning.*

Small Prepaid Advertisements *(for Rates see page xi.) are accepted up to 4:30 p.m. on Thursday.*

TECHNICAL PRINTING.

"The Electrician" Printing and Publishing Company (Limited) *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

The Electricians' Directory.

Royal 8vo. Cloth Boards, 3s. 6d., post free 4s.

At the commencement of each year is issued The Electricians' Directory and Handbook. *The Directory was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

THE DIRECTORY FOR 1889 IS IN PREPARATION,

And new names and addresses are now being received.

OVERHEAD WIRES FOR ELECTRIC LIGHTING.

In view of the extensive projects for lighting the metropolis by means of electricity now in course of development, it need not surprise us that the public are already alive to the question as to how the wiring is to be done. According to the *Standard* of Tuesday last questions are about to be put to the President of the Board of Trade with regard to the intentions of the newly-formed Electric Lighting Companies, it being feared that their plans will involve an enormous addition to the existing overhead wires. Probably the question of their safety will also be raised, and will have to be answered. The subject is of considerable importance at this juncture, and desiring that it may be dealt with in a thoroughly fair and unprejudiced manner we hasten to offer some observations upon it in the interests both of the undertakers and the public at large.

Much ill-feeling has been aroused by the unrestricted and unregulated proceedings of the Telephone Companies, whose overhead systems might have been rendered as inoffensive to public taste as they are harmless to public safety, had Parliament consented to grant legal rights—subject to reasonable restrictions—in the first instance. Left to themselves the companies allege that they have made the best of their position, and that they would have offended far less if their powers had been a little greater. In other words, their wires often follow fantastic and overcrowded routes, simply through the difficulty of obtaining way-leaves for less objectionable courses. No doubt this is true in many instances; and, at all events, the general result has been so unsatisfactory that the absence of legislative sanction and control has long been a matter of profound regret. That being the case, it is fortunate, perhaps, that in respect to overhead electric light wires the issue has been raised at an early stage, and hopes may be entertained that, acting on the powers conferred upon it by Parliament, the Board of Trade will, concurrently with its regulations, grant powers which will place the electric lighting industry on a better footing than the

Digitized by Google

telephone industry, both in respect to its rights and its duties. The Electric Light Companies will not object to regulations; and it will be seen from our last week's issue that the Board of Trade is far from objecting to regulate them; but something must be conceded in return, and if any doubt still exist as to whether the powers conferred by licenses and provisional orders for laying wires underground apply to their erection overhead now is the time to remove such doubt. We may say at once that we do not look to the overhead system alone for a complete solution of the problem of distributing electricity, but we do think that it will always find a place in high-tension systems. Probably the ultimate solution will consist in a combination of the two—underground conduits in the most crowded districts, and overhead lines for the outlying portions. But in the earlier stages of the enterprise it seems almost essential that overhead wires be largely resorted to. Gradually, as the business grows, they may be supplemented, if not superseded, by conduits or subways.

The alarm expressed in the *Standard's* notice that the number of overhead wires will be enormously increased has, however, but a slender foundation. In the first place, to provide individuals with separate telephone services a proportionate number of separate overhead wires is required; whereas, to supply the same number of individuals with electricity would require a very much smaller number of wires overhead, a single outgoing and return wire often serving for the needs of a whole district. In reality, what additions may be required for electric lighting purposes for a long time to come will make scarcely any appreciable difference to the overhead wire system of the metropolis. As to their relative safety, something may and probably will be said in opposition to the electric light wires. On this point we shall speak presently; but, as almost all the outdoor installations hitherto permitted have been on the overhead principle, and as no thoroughly satisfactory method of burying the wires underground has yet been devised, it is not to be supposed that the former system will be forbidden, or that electric lighting will be suppressed altogether, because its current is not perfectly harmless like that of telephony. For many reasons, apart from the question of safety, we have advocated the placing of wires underground in all populous towns; and to a very large extent this has been successfully accomplished by the Post Office Telegraph Department. But in this case the problem is of a very different and much more difficult character, and, although we are anxious to see the experiment of underground conduits for all kinds of conductors tried on a considerable scale, yet we cannot wish to see the progress of electric lighting delayed because of the few additional housetop wires which it would involve.

Of course the example of American cities, and particularly of New York, will be cited against us. There the electric wires of every description have been ordered underground; and in some places they have been summarily pulled down where the owners declined or neglected to obey the law. Misgivings, however, are already entertained that action in this matter has been too precipitate, and that to get rid of one form of nuisance the municipal authorities have exposed the public to another and perhaps a more dangerous one. The condition of the street wires in America was becoming simply intolerable. Our New York correspondent's letters have so graphically described the state of things arising out of unlimited competition among the telephone, telegraph, and electrical companies peculiar to the States, that we need not refer to it more particularly here. Necessary, however, as was some drastic measure of relief, and ingenious as have been the devices for lodging the offending wires beneath the pavements, the effect on lighting wires individually, and on signalling wires collectively, is by no means encouraging. To provide separate subways for these would be even more difficult in London than in New York, and they would certainly be exposed to the same sort of risks as those which are mentioned in our correspondent's letter from that city this week. Explosions of gas accumulated in the cable conduits are reported from New York, Boston, and elsewhere; and whether due to lightning or to other causes, such accidents sharply illustrate the troubles attending the laying of wires underground.

Any comparison, however, between this country and America at once provokes the observation that whatever we decide to do, whether we put our wires underground or carry them overhead, there is one thing we shall not do—we shall not scamp the work. Our own electrical engineers—we speak of men in the front rank of the profession—are not faultless; but their errors are chiefly due to lack of experience, never to culpable and reckless indifference to the consequences of bad workmanship. Now, these are precisely the terms we in this country would naturally apply to the installations of which we have authentic accounts from America. Of course, there are many conspicuous examples of an opposite kind which we ourselves are only too glad to imitate; but we have their own confession for it that in many instances the work of American electrical engineers is incomparably inferior to ours. A reference to Mr. HAROLD BROWN'S letter which we print this week affords some illustrations of the kind we allude to, and which he characterises in language which Englishmen will not consider too strong. Mr. BROWN'S facts and deductions as regards alternating currents may be taken with some allowance for his well-known prejudice against that system of supply; but there is plenty of independent testimony as to the "criminal carelessness" on which he so warmly animadverts. And what we have to say about it in relation to the matter now under discussion is that the dangers which the States have had to legislate upon are to a great extent non-existent and not to be apprehended here. More than one hundred miles of overhead electric light wires are already working in London alone, and there has been no serious accident traceable to bad workmanship, carelessness, or want of supervision. The Board of Trade can be trusted to frame and enforce regulations sufficiently strict; and with this guarantee the public may be content to allow the necessary erections for any electric light supply that London will require for some years to come.

MANUFACTURE OF COPPER WIRE BY ELMORE'S ELECTRO-BURNISHING PROCESS.

Messrs. Elmore, whose electro-burnishing process for the manufacture of copper pipes has been recently described in our columns, are now making wire for electrical purposes from the copper so obtained. The method adopted is by the use of a specially-constructed machine to cut the copper pipe made by their process into a wire of square section by a spiral cut running from end to end of the pipe. As this square wire is cut it is drawn through the first hole of a wire-drawing plate, and subsequently drawn down to any gauge required.

The copper has been submitted to a series of mechanical tests by Prof. Unwin and Prof. Kennedy, in the Engineering Laboratories of the Central Institution and of University College respectively, and also by Messrs. Clark, Forde and Taylor, and by Mr. C. J. Simmons, who have also submitted it to a series of tests for electrical conductivity.

The tensile strength of some of the specimens of hard copper was remarkably high, the greatest values being in the case of two strips tested by Prof. Unwin, the breaking strains for which were respectively 39·29 tons per square inch, with an

Digitized by Google

ultimate elongation of 5·1 per cent., and 41·28 tons per square inch, with an ultimate elongation of 7 per cent.

According to Messrs. Clark, Forde and Taylor's electrical tests on both annealed and hard-drawn wire, the mean value of the conductivity of the annealed wire in terms of Matthiessen's standard for annealed copper (taken as 100), and of the hard-drawn wire in terms of Matthiessen's standard for hard copper, in each case came out 102·38. The details of the experiments are given in the accompanying table :—

Diameter in inches.	Gauge (approximate) B.W.G.	Conductivity of annealed wire in terms of standard for annealed copper.	Conductivity of hard wire in terms of standard for hard copper.
0·113	12	102·33	102·46
0·0825	14	—	102·51
0·057	17	102·35	102·31
0·049	18	102·45	102·26

The temperature coefficient of this exceptionally pure copper is found to be distinctly higher than that given by Matthiessen for the purest copper he was able to obtain, a result which was to be expected.

ON THE CONDUCTION OF ALLOYS AND SOLID SULPHIDES.*

BY DR. J. H. GLADSTONE, F.R.S., AND W. HIBBERT.

This Paper concerns the nature of the conductivity of alloys and sulphides. They may either conduct the electric current directly, like metals, or electrolytically whilst they are undergoing decomposition. If a current is passed through an alloy any decomposition should manifest itself in a change in the resistance. The well-known alloys of lead, tin, cadmium, and bismuth, some of which melt in boiling water, exhibit no change of resistance if the current passes through them, or if any does appear it is very slight, and has nothing to do with the direction of the current. The alloys were contained in U-tubes. If, however, a little more lead, ½ per cent. or 1 per cent., was added to the alloy in the one limb a change was observed, though Prof. Roberts, in his allied experiments which were brought before the Manchester meeting, had not found any change. In another series of experiments solid particles, coarse or fine, of galena and other sulphides were packed with plates of bright silver between them, and the current passed through the group. Some of these sulphides are fairly good conductors. In a few cases the silver became a little tarnished; but, on the whole, the experiments prove that ordinary sulphides of the formula MS are real conductors, and not electrolytes. The cuprous and silver sulphides of the formula M_2S, on the contrary, behave like electrolytes. Thallium also forms a sulphur compound of the formula M_2S. It was therefore interesting to inquire into its behaviour; and it has been ascertained, as Prof. Crookes had already observed, that this sulphide becomes a better conductor at higher temperatures, and also that the polarisation increases. Another thallium compound, Tl_2S_3, is soft and plastic, and a very poor conductor. When placed in the tube with platinum or silver electrodes it showed a very slight polarisation at higher temperatures; but it became hard, indicating that a molecular change had occurred, which was not of the nature of a direct decomposition, as no sulphur could be extracted.

* Abstract of Paper read before the British Association meeting (Section A) at Bath, September, 1888.

The Montreux Disaster.—A *Times* telegram says that the accident at Montreux last week was due to the telephone. The reservoir which furnished the motive power of the Chillon electric tramway being so full as to cause apprehensions, the man in charge was telephoned to in the words, "Ne mettez plus d'eau." He did not catch the first two words, and consequently turned on more water; the result being that the reservoir burst, with loss of life and great damage to property.

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

At the meeting of the Society last week the following discussion took place upon Mr. Lant Carpenter's Paper "On Ocean Temperatures in Relation to Submarine Cables," which was published in our previous issue :—

Mr. ALEXANDER SIEMENS said that they had listened to an exceedingly interesting Paper from Mr. Carpenter, and with that gentleman's permission he would give some practical illustration of the ocean temperatures which his own firm had observed. He would use a diagram (Fig. 1) of temperatures which were observed at the Weston-Waterville section of the Commercial Cable Company, that company having given permission to publish it. The observations were made by Siemens Brothers' electrician, Mr. Frank Jacob. The length of the cable was about 320 nautical miles, and it enclosed two conductors. The method adopted to make the measurement was that for the conductor resistance the two cores were connected in series; and for the dielectric resistance the one pole of the battery was connected to one conductor and the other pole to the other conductor. That method of measurement was devised by Mr. Frank Jacob to eliminate the influence of earth currents. The lower curves on the diagram showed the variations in temperature throughout the three years, and gave the conductor resistance direct and as they were taken from the instrument. The upper curves showed the insulation resistance. The observations were taken as the mean of ten minutes' electrification by readings at intervals of every ten seconds, but as the earth currents were eliminated by the method of testing which he had described the electrification was as regular as when testing the cable at the works during the manufacture. These curves showed very accurate measurements through the fact of two cores being

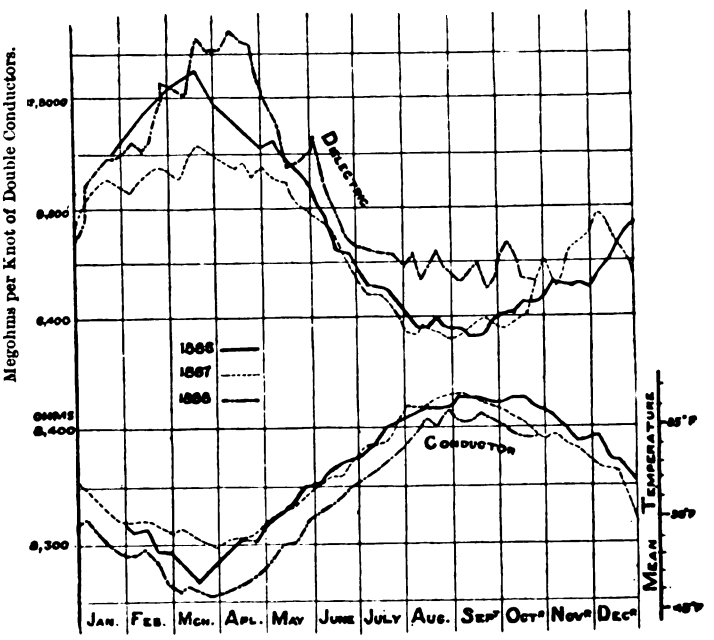

Fig. 1.—Annual Variation in Temperature, Weston-Waterville Cable.

available. In the diagram three curves were given representing the measurements for 1886, 1887 and 1888 respectively. The resistance of the copper conductor while the cable was being manufactured at the works was tested at a uniform resistance of 50°F., and by adding up the different lengths of the coils as they were tested the total resistance was arrived at, which represented 50°F. For instance, in the beginning of May, 1886 and 1887, the cable was exactly at the same temperature as in the tanks at the works. Then the well-known curve gave the variation in temperature. They would observe a very curious thing—that the observations in 1886 and 1887 were almost identical. In the beginning of June, they saw the two lines almost fall together, and in September the two lines were exceedingly similar. Then, a little further on, they would see that in 1888, which was rather a cold year, it showed a conductor resistance much lower all through the year, at least as far as the curve went, than it was in the two preceding years. Every variation in the conductor resistance was shown in the resistance of the dielectric, only it was always in the opposite direction. The maximum and the minimum they would see was in March and in September, in all three years. In March the water was coldest, in September the water was hottest. If the temperatures all along the cable had been exactly alike, the temperature calculated from the copper resistance and the temperature calculated from the resistance of the dielectric would be the same. But that was not the case. That seemed to show that the water for the whole length of the cable was not at a uniform temperature; in October, 1886, a measurement was taken at 120 miles from the Irish end by a thermometer in the way described by Mr. Carpenter. The actual temperature was found to be 52°F., whereas the resistance of the cable gave 56°F. This discrepancy seemed to point out that the waters of the Bristol Channel had a great influence, and varied.

Digitized by Google

more during the year in their temperature than the water of the deeper section cable. It was, perhaps, useful to point out that at 50°F. the insulation resistance was just over 70 megohms for the total length of 320 knots. They must bear in mind that he had two conductors connected to the instrument; therefore the insulation resistance per knot was 70 times 160, or 11,200 megohms. In a similar manner Mr. Jacob had furnished him with the average temperature of some of the Atlantic cables which his own firm had laid, and it was curious that in four of them the average temperature came out as 37°F. and in the fifth it was 38°—it lay in so much shallower water. Of course, in these measurements the shore ends were included, and therefore the temperature was a little higher than Mr. Carpenter had shown the temperature of the bottom of the Atlantic to be; but if they bore in mind that there were these shore ends he thought that the agreement of the two measurements was very close (applause).

The PRESIDENT: What is the greatest depth you got when the Weston-Waterville was laid?

Mr. SIEMENS: Only 100 fathoms.

Mr. STALLIBRASS thought the Siemens electrical thermometer had not been used as much as it should have been. On the telegraph ships there was every facility for using this thermometer, and he was sure that excellent results would be got from it. He thought that the Miller-Casella thermometer had many disadvantages. It required great care to successfully use this thermometer. Very often the indices moved with the least jerk, and except in careful hands he thought the thermometer was to a certain extent unreliable. The Siemens thermometer had many advantages. For shallow water he thought that the capsizing Negretti and Zambra thermometer was, perhaps, more suitable, and he preferred to use it with the leaden messenger, which travelled down the sounding line and released the locking arrangement. He thought if this thermometer was used to any extent it would be worth while to have a correction table. Although the amount of mercury which was measured on the capsising of the instrument was very small, still it was affected by temperature, and if, as he had often seen the thermometer used, it was read to a temperature of considerably over 80 degrees, the expansion of that comparatively small amount of mercury was well worth considering. A friend of his had experimented on this in his laboratory and had made a correction table, but he did not think it had ever been used (applause).

Mr. ALEXANDER SIEMENS: We have also a temperature calculation —66°F.—about a cable which is laid in the Red Sea, and I will add the result to my remarks in the *Journal*, so as to put on record how that agrees with the measurements spoken to by Mr. Carpenter.

Captain WHARTON said that he had very little to remark strictly germane to the subject of the Paper—that was, anything in connection with the submarine cables, of which he knew nothing. He could only say a few words about the apparatus that was used to ascertain the temperatures. He thoroughly agreed with the last speaker that the Miller-Casella had disadvantages (he would not say many disadvantages, however), and that if they could get a more perfect instrument they would gladly use it. The Magnaghi instrument did not answer in deep water. Their experiments tended to show that in about two out of three soundings the thermometer reversed at some point before the one at which they wished it to reverse, and when it came up showed entirely wrong. They had, therefore, more or less discarded it as being entirely unreliable; but the Miller-Casella gave very good results at a general depth. Of course if there was a colder stratum above a hotter no doubt the result was unreliable, but it was very rarely that the indices got shaken down—at least, they had found it so. When the serial temperature was taken, they could judge very fairly from that alone whether any particular observation was incorrect, and it was very rarely indeed, owing to the perfection with which these thermometers are made, that those errors were apparent, and for the present he did not think that they could have any better instrument. He was not acquainted with Sir William Siemens's beautiful sounding instrument; but he was afraid that it was hardly adapted for use on board their vessels, where they had not electric apparatus nor officers sufficiently trained in electricity to use it. He had last week received a letter from one of their surveying vessels in the South Pacific. Captain Aldrich wrote that he had obtained a very deep sounding of 4,430 fathoms to the south of the Friendly Islands, and that he was lucky enough to bring up his thermometer from the bottom quite safe. In the soundings of the "Challenger" at nearly the same depth four thermometers were sent to the bottom, and three of them came up broken. Captain Aldrich only sent one of them to the bottom, and he was lucky enough to bring it up safe with a temperature of 33·7.

Mr. CHARLES BRIGHT: As regards the conductivity of copper, referred to by Mr. Lant Carpenter, I would remark that the 102·38 per cent. mentioned by him is at the present time quite an ordinary conductivity for copper intended for telegraphic purposes, and, consequently, the correct coefficient for variation of resistance by temperature is frequently somewhat higher than that given for Dr. Mathiessen's standard, pointing to the desirability of a fresh standard being adopted. Inasmuch as the resistance of gutta-percha is effected so much more sensitively by a change of temperature than that of copper, it is sometimes a good plan to calculate the temperature by the variation of the dielectric resistance in the case of gutta-percha cores, as well as by that of the conductor, merely as an occasional check on the coefficient for variation by temperature of the resistance of the copper conductor. By reason of the effect of pressure on the resistance of gutta-percha too much reliance cannot be put in such results, especially owing to the possibility of the presence of an incipient fault. Moreover, this plan is not, as a rule, carried out in submarine cores, owing to the additional effect of the weight or pressure of the water above the cable on the resistance of any fibrous materials such as gutta-percha, and to the fact that no such effect occurs visibly on any metal substances, such as copper, whose hardness prevents their being condensed by any physical agencies. No theory has been advanced in the Paper as to the different physical effect produced by a change of temperature which causes the resistance of metals such as copper to be decreased by a cold temperature, and that of vegetable fibrous substances, like gutta-percha or India-rubber, to be increased thereby, and *vice versâ*. The physical effect is presumably the same in both cases as that of the pressure of the water, only materially more marked. The effect of pressure is that of condensation. In the case of a metal no sensible change is produced thereby owing to the already highly condensed state; but with vegetable fibrous substances, like gutta-percha and India-rubber, the effect is highly sensible. These materials are naturally of a porous character, but when subjected to pressure become less so, and consequently tend to absorb less water, the presence of which, especially as regards salt water, naturally lowers the resistance of such materials; moreover, the mere fact of increased homogeneity is sufficient to account for increased resistance by less loss of current laterally. The late Sir William Siemens first demonstrated the effect of pressure on insulating substances in a Paper on the subject read before the British Association, in 1863, based on experiments on the gutta-percha core of the Malta-Alexandria cable of the year before, as well as on the Carthegena-Oran gutta-percha core and on certain India-rubber cores. Herein he pointed out how the resistance of gutta-percha was materially increased by pressure and in direct proportion to the degree of the same, which was varied as desired in the pressure tanks of Reid. The formula given in the Paper before us, expressing the increase of the resistance of gutta-percha by pressure, was given by Siemens as the result based on these experiments, where the coefficient 0·00023 was the amount of increase in resistance found to occur on a unit resistance by a unit pound pressure. It will be seen, therefore, that this formula was not one of the many introductions due to Mr. Latimer Clark, as stated in the Paper, but is due rather to Sir W. Siemens. Messrs. Bright and Clark tested the first Persian Gulf core under pressure, finding the gutta-percha to be increased in resistance 2·6 per cent. for every 100lb. pressure; whereas Siemen's experiments showed the dielectric resistance of the Malta-Alexandria core to be increased only 2·3 per cent. thereby. In Bright and Clark's experiments 600lb. was, however, the maximum pressure, being equivalent to only 224 fathoms of sea water, whereas in those of Siemens a pressure equal to about 1,700 fathoms was applied. The most useful way in practice of expressing the increase of the resistance of gutta-percha by pressure on submergence is, I think, to say that it is increased 6·2 per cent. for every 100 fathoms depth of sea water. Most forms of India-rubber cores are more absorptive than a gutta-percha core, owing largely to the fact that the rubber, as a rule, is of necessity laid on the wire in strips either spirally or longitudinally, thus involving a continuous seam, instead of being applied round the wire in a homogeneous tubular form, as in the case of a gutta-percha core. Siemens found that some forms of masticated India-rubber were decreased in resistance by pressure at a rate about one-fourth that at which gutta-percha is increased by a corresponding amount. The formula expressing the decrease of resistance of such India-rubber by pressure would be

$$R_p = R\,[1 - (0{\cdot}000061 \times p\ \text{lb.})],$$

where R is the original resistance, 0·000061 the coefficient of decrease of resistance on unit resistance (1 megohm) by unit pressure (1lb.), p the number of pounds pressure applied, and R, the increased resistance by pressure. Fairbairn found that some forms of India-rubber were slightly increased in resistance by pressure. In any case the resistance of any description of India-rubber can be but little improved by pressure due to submergence, as compared with gutta-percha, owing to its higher absorptive power. Most mixtures of vulcanised India-rubber, being more homogeneous and less absorptive (like gutta-percha), are not, however, affected materially by pressure in either direction. The nature of the physical change produced by a change of temperature on vegetable substances of the gutta-percha and India-rubber order is that of cold contracting the material and heat expanding it. Thus, by contraction the pores of the material are closed by its molecules being brought closer together, and consequently it is more compact in its texture, its absorptive tendency is proportionally decreased, and as a result the electrical conductivity is decreased. The effect of heat on fibrous materials such as gutta-percha and India-rubber is that of expansion separating the pores and thus increasing the absorptive tendency and lowering the resistance by this and by the decreased homogeneity of the texture. The fact that temperature exerts an opposite influence on the conductivity of metals and vegetable materials cannot be satisfactorily explained physically. In 1863, Messrs. Bright and Clark conducted a series of experiments on the gutta-percha core of the Persian Gulf cable in order to determine precisely the nature and degree of the variation of the resistance of gutta-percha due to temperature. The result of these experiments showed that the resistance of gutta-percha was increased very considerably by a decrease of temperature, and *vice versâ*—not in simple proportion to each alteration of temperature, but by compound interest, as shown in the logarithmic curve in the diagram before us, similar to that which was drawn up as the result of these experiments. The resistance of India-rubber is somewhat similarly increased by a fall of temperature and decreased by a rise thereof, but mixtures of India-rubber when vulcanised are considerably less affected by temperature than gutta-percha; indeed, the coefficient for variation of resistance by temperature of the favourite form of Hooper's vulcanised rubber is less than half that denoting the variation of gutta-percha resistance. The degree of variation of resistance by temperature (as also by pressure) of India-rubber, even when vulcanised, differs very much, however, for the different "mixtures." The amount of variation by pressure and temperature depends principally on the degree of specific resistance; thus, mixtures with a low resistance are very much more affected than those with a very high resistance (in the same way that gutta-percha, which has a much lower resistance than Hooper's rubber, is more affected by temperature). Thus the coefficient for

Digitized by Google

variation of resistance by temperature of some forms of vulcanised India-rubber with a resistance but little above that of gutta-percha is more than double that for vulcanised rubber with the highest resistance (which is often twenty times as much as that of gutta-percha at 75°F.) or nearly as much as that for gutta-percha. The same applies, only to a less extent, as regards the different gums of gutta-percha. For this reason, the coefficient of variation of resistance, represented by the curve in the diagram before us, cannot be said to apply to gutta-percha in general, but only to the particular gum on which the experiments were made from which the coefficients corresponding to the curve were deduced. Owing to the alteration in the gums at different times it would be desirable, strictly speaking, to calculate a separate coefficient for variation of resistance by temperature for each separate core made. Considering, however, that the resistance of gutta-percha varies so much by age, owing to other circumstances besides changes of temperature, such calculations and corrections of resistance for temperature can only be correct for the time being—*i.e.*, at which the variation of resistance by temperature was noted. I do not think this fact is sufficiently appreciated. Temperature affects the electrostatic capacity of a cable in so far as it affects the resistance of the insulating medium; that is to say, materials with the highest resistance usually offer facilities for the lowest capacity, and *vice versâ*. Moreover, when the resistance of gutta-percha is increased, as by a decrease of temperature, its capacity also is, as a result, at the same time decreased (owing to a specific change in the material), though in a much less degree. It would probably be decreased in a much more proportional degree to the increase of resistance but for the fact of the cold temperature having also, by contraction, the effect of bringing the two plates of the Leyden jar closer together. The capacity of India-rubber is less altered than gutta-percha by temperature; in fact, scarcely at all. Some mixtures are increased and others decreased in capacity thereby; but all in a very small degree. In his experiments with pressure, Sir W. Siemens did not find that the capacity of either gutta-percha or India-rubber was affected by pressure. It is probable, however, that pressure, inasmuch as it increases the resistance of gutta-percha, will, like a cold temperature, tend, indirectly, to be the cause of a slight decrease of capacity; but whereas pressure produces so much less effect than temperature on the resistance of gutta-percha, its effect on the capacity is imperceptible; indeed, the same counteracting tendency by condensation of the Leyden jar taking place, the capacity can, in any case, be but very slightly effected by pressure. Inasmuch as pressure tends to decrease the resistance of some forms of India-rubber it also tends to increase the capacity thereof, in the same way that a cold temperature does. When a cable with a gutta-percha insulator is submerged under a depth of 2,000 fathoms of the ocean, where the temperature is 36°F., and where the weight of sea water above it is equivalent to 5,352lb. per square inch, the insulation resistance is increased 1,145 per cent., of which 1,022 per cent. is due to the decrease of temperature from 75°F. to 36°F., and 123 per cent. to the pressure exerted on it. Thus the decrease of temperature has taken a nearly 10 times greater share in the increase of resistance than the pressure has. To take a practical example:—An original resistance of 600 megohms per knot at 75°F. at atmospheric pressure, becomes at this depth 7470·5 megohms per knot, equivalent to an increase of 6870·6 megohms, 6,737 of which is due to temperature and 738·6 to pressure. In many waters, however (such as in the Atlantic, for instance), the temperature does not fall below the said 36° F. which it very ordinarily attains at about the aforesaid 2,000 fathoms depth, so that in the case of submergence under greater depths the resistance of the dielectric will be no further increased by temperature, though it will continue to be increased by pressure in direct proportion to the increase of depth. Thus, when the same cable is submerged under a depth of 3,000 fathoms in a case where the bottom temperature at this depth is 36°F., and where the pressure of a column of water of this height is 8,028lb. to the square inch, then the resistance will by pressure be further increased by 4,598 megohms, *i.e.*, from 7470·6 megohms at 2,000 fathoms to 12068·5 at 3,000 fathoms. Thus the total increase of resistance due to the pressure of this depth is 5,336 megohms, or 889 per cent., whereas that due to the 39° decrease of temperature from 75°F. to 36°F. is 6,132 megohms, or 1,022 per cent. From this it will be seen that there is thus a material reduction in the difference between the relative effects of temperature and pressure at 3,000 fathoms as compared with that at 2,000 fathoms. In fact, at great depths pressure takes nearly as much part in increasing the dielectric resistance of a cable as temperature does, which, though it falls rapidly just below the surface, does so very gradually lower down until at a certain depth it falls no further. Vulcanised India-rubber cores especially are nearly as much decreased in dielectric resistance by pressure at great depths as by temperature, and at depths beyond 3,000 fathoms the effect of pressure is, under some circumstances, even greater than that of temperature probably.

Dr. OBACH said that some two years ago he made experiments with a number of thermometers to find out what influence pressure had on the readings. Of course, he had only low pressures at his disposal in the laboratory, but the results would give some idea as to how greatly thermometers could be influenced by pressure. He found that when a delicate chemical thermometer divided into tenths of degrees was placed in a vacuum, the mercury fell between one and two tenths of a degree, and when the pressure was increased one atmosphere it rose to about the same extent. All the thermometers behaved similarly. Therefore, for these thermometers one could only say that a difference in pressure of two atmospheres produces a difference in the reading of one-fourth to one-third of a degree centigrade, so that a pretty high influence is exercised in this way; which, for some experiments of importance—for instance, distillations in vacuo—necessitates a correction which cannot be neglected (applause).

Mr. REDGRAVE, a visitor, having obtained permission to address the meeting, said he had been engaged on many cable expeditions for one of the largest firms in the country. In taking their deep-sea temperatures they used a form of thermometer similar to the Miller-Casella made by Elliott Bros. With this instrument they had obtained temperatures in all depths from 500 to 2,500 fathoms, and had never seen a thermometer broken yet. Captain Wharton had told the meeting that a friend of his had been lucky enough to recover a thermometer from a great depth, and he had repeated the word "lucky." He (Mr. Redgrave) thought that was a very apt expression, as in taking temperatures with the thermometers attached to the ordinary sounding wire it was doubtful, at least, if you would ever recover them from deep water. On one or two occasions they had put down thermometers on deep sea buoy moorings. He remembered one case where a thermometer was down for three weeks. They could not say for certain that the stratum at the bottom was the coldest; but, assuming it to be so, and without any further correction for the instrument than comparing it with a standard, at a depth of 2,200 fathoms it recorded 37deg. He thought that bore out Mr. Lant-Carpenter's results closely. As regarded the temperature shown at the western end of the Atlantic diagram, he would like to mention a fact probably unknown to many present. The copper resistance of a 3-cored cable laid along the Nova Scotian coast showed a temperature of 29°·5 in the month of August. Having three conductors they had special facilities for checking this result, and although it was discredited by many at the time, the test was repeated and confirmed by an eminent electrician (now dead), Mr. J. C. Laws. Mr. Lant-Carpenter's explanation of the existence of that cold shelf of water would account for this phenomenon.

Captain WHARTON explained that in using the word lucky he had referred to the very great depth, which induced a pressure of five tons upon the thermometer, which was a very different thing to the 2½ tons to which Mr. Redgrave's thermometer was subjected. He thought it was a triumph to have constructed an instrument which was able to stand such an enormous pressure. They used galvanised wire, and they sent down their thermometers without the slightest fear of the result. Captain Aldrich had taken something like 80 to 85 soundings (varying from 1,000 to 4,000 fathoms) in the Indian and Pacific Oceans, and he had only lost three thermometers.

Mr. CARPENTER, in reply, thanked Mr. Siemens and Mr. Redgrave for their interesting observations. The fact of being able to practically ascertain the temperature of the sea by observations on the electrical condition of a cable was exceedingly interesting, and a capital proof of the wonderful perfection to which electrical measurements had now attained. He was not quite sure whether Mr. Siemens had made it clear that the cable to which that gentleman had referred lay in really shallow water, the depth not being greater than 100 fathoms. A great deal of what had been given in the Paper related to water at very much greater depths than that. One result of the cable being in such shallow water was that it was affected by variations in the temperature of the air above the water. As far as he remembered, he believed, the conclusions arrived at in the "Challenger" and other observations was that what might be called the super-heating effect of the sun's rays did not reach lower than about 100 fathoms. They, therefore, had in their shallow-water cable a most interesting and beautiful example and illustration of the effect of air temperatures upon the water below. With regard to what Mr. Bright had said, he would point out that he was careful, in alluding to the diagram, to say that it applied to one particular cable, and he gave the name of the cable, and the particulars of it. He did not mean to imply that that should be taken as an average of insulators; but simply as one insulator, and he was quite aware that various insulators had their separate coefficients of change with regard to change of temperature. He thanked Mr. Bright for the correction that gentleman had given him with regard to the pressure law, with which he had associated the name of Dr. Latimer Clark, and he was glad to find that a great deal of the result was due to one whose memory they all respected and revered, Sir William Siemens (applause). With regard to Mr. Mordey's question, he was not aware that observations of the kind alluded to by that gentleman had been taken, although it was quite possible that they might have been. In conclusion, he thanked the meeting for the way in which they had listened to a Paper which some of them, perhaps, might have thought was a little outside the usual run of the Society's Papers (applause).

The PRESIDENT: Gentlemen, we have listened to a clear and very able Paper of a class rarely introduced to our notice, and yet particularly interesting to one section of the members of our Society—those who are engaged in submarine enterprises. I think it is well that we should at times have something especially adapted to the tastes and interests of the various classes of our members, and I thank Mr. Carpenter for having introduced it to us. I beg, therefore, to propose that you will present to him a hearty and sincere vote of thanks for the Paper which he has been kind enough to read this evening.

The vote was carried by acclamation, and the meeting adjourned to the 22nd inst.

The Electric Light at the Empire Theatre.—The success of the new ballet at the Empire Theatre is considerably enhanced by the large scale upon which the electric light has been made use of. Each of the fifty-eight members of the *corps de ballet* is supplied with a small electric lamp in the hair, the current being obtained from a small primary battery of four cells attached to the waist. These cells only weigh 3lbs., and measure about 3½in. by 2½in. The electrical arrangements are under the supervision of Mr. Richard Allbright.

ELECTRIC TRACTION IN BIRMINGHAM.—TRIAL OF THE JULIEN CAR.

The first public trial of electricity as a motor for tramway purposes in Birmingham was made on Wednesday of last week upon the lines of the Central Tramways Company. In our issue of October 26th we gave some details of a private trial of the same car which we had recently witnessed, but the following additional particulars will be of interest. The motor, which was specially designed and built by Elwell-Parker (Limited), has a 14in. armature, and at 700 revolutions with 200 amperes is capable of developing a maximum of 40 horse-power for a short time. Its normal output is, however, only six or seven horse-power. The accumulators are 104 in number, with 39 plates in each cell, measuring 9in. by 6in. A switch is arranged to connect them all in parallel or all in series or in two intermediate groups. Double helical toothed-wheel gearing is employed, with satisfactory results. The surfaces of the teeth, which come into contact from an obtuse angle, and the cogs themselves take the shape of a right and left-handed screw. The result is that the rolling contact is practically perfect, and the strain is always distributed over several teeth. There are other improvements in detail in connection with this gearing which, however, are not yet patented. The engine is about half as long as an ordinary steam tram-car, and, like a steam engine, is enveloped with a covering which reaches within a few inches of the metals.

The conditions laid down by the Birmingham Central Tramways Company were that the engine should be able to draw the existing cars, without alteration or conversion of form, along any of their steam routes; that the cost of traction and depreciation should not exceed that of steam locomotion; and that the electrical engine should be able to perform a full day's work of sixty miles without recharge. Those familiar with the steep gradients on some of the company's lines—Bradford-street, for instance—will be alive to the difficulty experienced in meeting the requirements of the company. The engine weighs about 8½ tons, and the accumulators are large enough to enable it to perform a journey of between seventy and eighty miles. A car similar to those working on the cable tramway was attached to the engine, and was filled inside and out with passengers, including the Mayor and several members and officers of the Corporation, and directors of the company. A start was effected at about twenty minutes to three, and the engine and car proceeded at the ordinary pace of a steam engine, observing all the stops, to the town end of Bradford-street. It was felt that the crucial test was the Bradford-street-Hill, and many misgivings were expressed as to the engine mounting the severe gradient of one in seventeen. The engine, however, acquitted itself to the satisfaction of all, mounting the hill at a fair speed. The rest of the journey was easily performed without any hitch, the engine and car running into the Moseley depôt twenty-eight minutes after the start, the average time taken for the run by a steam engine.

Those who had ridden on the car then adjourned to a waiting room, and Mr. J. SMITH made a few remarks, in the course of which he explained that the Central Tramways Company were making the experiments with a view to testing the possibilities of electricity as a motor. The engine they had seen at work that day was not the ideal one—namely, the car with the motor self-contained; but half a loaf was better than no bread, and what the Central Company desired was to ascertain whether electricity could be used in the form of accumulators, could be worked at a reasonable cost, with certainty and safety, with advantage to the travelling public, and with satisfaction to the authorities of Birmingham and the district. He thought that he ought not to conclude without referring to the firm of Elwell and Parker, who had supplied the car, to the latter of whom the company owed a considerable debt of gratitude for the trouble he had taken in the matter.

Mr. PARKER, in answer to questions, said that the engine could be stored with electricity between the time it was taken in the shed at night and the time of leaving next morning. The motive power required to draw the car up Bradford-street that afternoon was about 30 horse-power. There would be less wear and tear on the metals, because the engine was nearly five tons lighter than a steam-engine.

Councillor LAWLEY PARKER, speaking for the Corporation and and other local authorities, said that he thought he was right in saying that they would rather have a car with a self-contained motor.

Mr. SMITH said that he felt sure that whilst the Corporation and other local authorities wished to take care of the convenience of the public they did not desire to lay down conditions which would make tramway traffic a loss.

Mr. HUGHES, on behalf of the Handsworth authorities, said that he should feel very grateful if the company used engines similar to that tried that afternoon upon lines in their district, for the nuisances most complained of, arising from the emission of steam and sulphur, would be done away with.

A question was asked as to the cost of electricity as compared with steam, and

Mr. SMITH said that were the cost a little greater he should not hesitate to advise his company to face any moderate expense, in the full confidence that the increased comfort of travelling, especially to the outside passengers, would induce such an increase of traffic as would recompense the company for that increased cost. At the same time he did not see, making every provision for depreciation, why the working should not be found to compare with steam in regard to cheapness.

Those present then took their places on the car and were taken back to town.

LEGAL INTELLIGENCE.

Re the Faure Electric Accumulator Company: Judgment.

In the Chancery Division of the High Court of Justice, on Tuesday last, Mr. Justice Kay delivered judgment on the summons taken out by the liquidator of the Faure Electric Accumulator Company (Limited) against the directors.

Mr. JUSTICE KAY: The liquidator of this company, which is being wound up in this court, has taken out the present summons against certain gentlemen who were formerly directors of the company, under Section 165 of the Companies Act, 1862, seeking to make them personally liable for alleged misfeasance as such directors. No imputation whatever is made on the honesty or honourable conduct of any of these gentlemen; but it is alleged that they have committed breaches of trust in making certain payments out of the moneys of the company, and in permitting the transfer of certain of its shares. The Faure Electric Accumulator Company was formed on May 13th, 1882, for the purpose of making and carrying out an agreement for the purchase of certain patents, and carrying on the business of electricians and other matters. The capital was £1,000,000, divided into 80,000 Ordinary shares of £10 each and 200,000 Deferred shares of £1 each. Article 92 authorised the directors, out of the funds of the company, to pay the necessary legal and other expenses of and incident to the promotion, formation, and registration of the company, and all other preliminary expenses of the company. Article 28 is:—"No transfer of shares not being fully paid up shall be registered unless and until the transferee is approved by the Board of directors, and the Board at their discretion may decline to register any transfer of shares upon which the company has a lien." On February 15th, 1882, the company entered into an agreement for the purchase of certain patents under which payments had to be made in shares of the company. 20,108 shares of £10 each were subsequently allotted to the general public, and in this manner all the original £10 share capital was issued except about 20,000 shares. It appears that the company got into litigation in May of that year with another company, who, they alleged, were infringing their powers. M. Philippart, who, it seems, was very familiar with the working of these patents, attended in that month at a meeting of the Board, accompanied by Mr. Pincoffs, a London stockbroker, who acted as his interpreter. Philippart was a holder both of original and Deferred shares. He had made himself very active in the company's affairs, and upon May 22, 1882, he wrote to the Board offering to take up the subscribed capital of the first issue—that is, of the £10 shares—by taking 5,000 shares himself and 5,000 by his friends, on condition that his friends should have the option till June 15 of taking up the remaining 10,000 shares, and that he (M. Philippart) should be elected a director, and that no brokerage should be paid in respect of the allotment of these shares. This was considered at a Board meeting on the next day, May 23, and declined. On that day Pincoffs wrote to the company:—"I beg to offer to place 7,500 shares of your company at par upon condition of your giving my client the option of taking the remaining 12,382 unapplied-for shares at par until June 23 next, and subject to the usual brokerage of 2s. 6d. per share to myself." The Board appear to have taken the advice of their solicitor, who advised them by a letter, which is in evidence, that there was no objection in law to the acceptance of this offer, provided the Board were satisfied of the allottee, and that the brokerage was paid by the company, and not deducted from the price of issue. Thereupon the Board assented to the proposal, and later in the day a letter was handed to them from Mr. Morris, a stockbroker, stating that he was willing to take 7,500 shares at par, and pay £2 at once, provided he had the option of taking at par on or before June 23 the balance of the unallotted shares, amounting to about 12,500, and that the Board would allow 5s. per share commission on the whole number of shares taken by him, the commission on the 7,500 to be paid at once, the commission on the shares to be paid to Mr. Pincoffs. It is stated in evidence that Morris was known to the directors to be a stock-jobber of very large means. A formal application followed, and on the same May 23 the directors allotted 7,500 £10 shares to Mr. Morris, and paid £937. 10s. to Pincoffs as commission. Subsequently, about June 17, they allotted the remaining 12,382 £10 shares to Morris, and paid £1,547. 15s. as commission to Pincoffs. They received from Morris £2 a share on this allotment—that is, nearly £40,000. In the meantime the Board, on May 24, 1882, had received notice of a charge by Philippart to Lever on all his shares in the company, and on May 30th, 1882, they had notice of an injunction as to the Deferred shares of Philippart in the company. They referred this to their solicitor, who wrote on June 17th, 1882: "The directors should consider whether in the circumstances any tranfer of shares to M. Philippart should be registered before being fully paid." On June 30th, 1882, M. Philippart was elected

Digitized by Google

a director of the company. On September 27th the company had notice of two charging orders on M. Philippart's shares for £420 and £1,355 respectively. Mr. Morris seems to have been at this time in communication with the Board. He had been called on by them to advise, he having a large stake in the company. It appears he was desirous to transfer the shares he held, and on October 11th, 1882, the Board sanctioned, and subsequently passed a transfer of about 19,528 shares from Mr. Morris to M. Philippart. The transfer was completed on October 18th. Shortly afterwards the directors against whom this claim is made resigned. A call of £1 per share had been made, and on January 3rd, 1883, M. Philippart and his brother directors forfeited his shares, which were then about 18,500 in number, for non-payment of that call. Subsequently two other calls of £1 a share were made. On April 10, 1883, M. Philippart became bankrupt. In July, 1884, a winding-up order was made. Thirty shillings have been called up in the liquidation. The debts of the company, it is admitted, have all been paid. Claims to a large amount are outstanding, which the liquidator is resisting, and there are, I am told, some costs of the liquidation still to be provided for. The claims made by this summons are: first, damages for the alleged misfeasance of the former directors in allotting the 7,500 shares on May 25, 1882, and 12,372 shares on June 17, 1882, to Mr. Morris, a nominee of M. Philippart, or in allowing 18,500 of such shares to be transferred on October 18, 1882, to M. Philippart; and, secondly, that they may be ordered to repay the sum paid to M. Philippart for brokerage on such allotments, with interest.

His lordship, having considered the first part of the case in detail, said: I have no doubt that when the question concerning the transfer arose, it seemed to them they had no valid reason for not approving him as a transferee; they knew that he could not obtain a transfer from Morris without satisfying the very large sum of £40,000 which Morris had paid to the company. He did this, to some extent, by transferring other shares to Morris, but he must have provided a large sum in cash. Anything like corruption or dishonesty on the part of the directors being out of the question, I am unable to treat them as responsible for the consequences of permitting this transfer. Even if the act were, with the knowledge they had at the time, a grave error of judgment, there is no ground on which the Court could properly hold them liable. Upon the second point the learned judge said that he had felt much more difficulty.

Having dealt with the various aspects of the case at considerable length, he proceeded as follows:—I must declare that the respondents, the directors, who made these payments are jointly and severally liable to repay the same to the company, with interest at 4 per cent. per annum since the moneys were paid. The order will be this. The respondents (other than Philippart, against whom no relief is asked, because he is insolvent, and Mr. Ponsonby, who was not a director until after the allotment of these shares) must be ordered jointly and severally to repay the amounts paid to Pincoffs, with interest at 4 per cent. Then I refuse the summons with costs as to all the rest, except the second head, which I allow with costs; these costs to be set-off. I must direct the taxing-master to allow Mr. Ponsonby any separate costs that may be incurred—that is, any increase of costs (perhaps that is the better way to put it) by making him a respondent. The liquidator may take any costs out of the estate which may remain after the set-off, except that I must direct the taxing-master to disallow any costs of the cross-examination which he may consider excessive.

Anglo-American Brush Electric Light Corporation v. Orient Steam Navigation Company.

In this action, which came before Mr. Justice Chitty in the Court of Chancery on Tuesday last, the plaintiffs sought an injunction to restrain the defendants from an alleged infringement of their patent for the "compound winding of dynamos." The machines in question had been supplied by Messrs. King, Brown and Co., of Edinburgh, against whom the plaintiffs have entered an action in the Scotch courts. The defendants did not seriously contest the case, and in the end an injunction was issued against the infringement, an inquiry into damages was ordered, and a certificate of validity granted. The effect of this certificate is that the appeal only lies to the House of Lords. The defendants were also condemned in costs.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *November 3rd*, 1888.

A bad explosion in one of our down-town electrical subways a week or two ago, followed up very closely by one in Boston, has gone to show that our underground systems are not yet all that can be desired. The explosion in this city—due, it is supposed, to the ignition of gas by lightning entering along the cables—was so powerful as to lift the covers of two manholes several feet in the air, and to disrupt the paving in every direction. Evidently the precautions against the accumulation of gas are far from sufficient. The result of such an accident must be to render the conduit liable to a free inflow of both gas and water, so that it practically becomes useless. This view of the case has arrested public attention, and a more serious trouble has now developed in connection with the local Steam Heating Company. A pedestrian in the lower Broadway and its side streets, almost any day of the year, will have his eye caught here and there along the roadbeds by little jets of steam. The first suggestion to the inexperinced mind is that New York is built over a volcano, but the simple explanation of the matter is that these jets of steam come from the defective pipes of the Steam Heating Company. The effect of this escape of steam upon the wires and cables that have been placed underground has been most serious, and it is difficult to exaggerate it. I have myself a great many times passed one of the manhole covers on Broadway, and listened to the boiling going on underneath, not daring to put my hand on the manhole cover, so hot was it. From the tests made it has been proved that the temperature in some of the conduit manholes, affected by the steam leaks, has run up as high as 209 degrees. The Western Union Company has entered a warm protest against this condition of affairs, and has reported that its cables have been reduced to the consistency of jelly, and virtually boiled to pieces, so that the only remedy seems to lie in putting the cables overhead again. The president of the Steam Heating Company has hastened to explain that the trouble has been due to the use of wooden wedges instead of cast iron for holding the pipes together. The wooden wedges have shrunk from age and heat, and left the joints of the pipes open, requiring an outlay on the down-town mains in repairs of £50,000. This is an explanation which does not help matters much, as the trouble still continues. The only way out of the difficulty is either to stop the steam heating business, or not to attempt to lay electrical conduits where the steam pipes are already underground. The Board of Electrical Control will have to deal with this matter very sternly and determinedly, or there is a great probability that much of its work will soon be reduced to ridiculous failure.

A great deal of interest is taken by the public in the new electric road which is about to be run through Fulton-street, one of our busiest thoroughfares, and well as one of our narrowest and steepest. This road, for which the tracks are already laid, will be built by the Bentley-Knight Electric Company, and the conduit system will be used, the conduit having still to be laid, although immediate work on it is promised. The road will not be a long one, but from the fact that it will operate in a street which is always crowded with drays and trucks, and which in winter is liable to swamping from rain storms and snow thaws, it will be a difficult piece of work, and if successful will do much to advance the electrical conduit system in popular esteem. The material for the construction of the road is all ready, and the construction will be carried on as soon as it can be put on the ground. The site for the erection of the dynamos, boilers, &c., is virtually decided upon, and the cars which have been ordered are to be ready by December. This is another case in which the introduction of electrical appliances involves the ripping up of the street, but it is taken for granted that there is no help for it.

A recent decision in Chicago forces the last opponents of the American Bell Telephone Company to their knees, and practically wipes out all competition. It will be remembered that a little while ago a decision was rendered against the Cushman Company on the ground of infringement of Bell's patent. In spite of this decision, the Cushman people continued to operate their telephones in various places, and hence it was necessary to seek for another injunction. The contention of the defendants was that the licensees of the Bell Telephone Company had withdrawn their instruments from the towns where the infringing apparatus was at work, on the passage of a State law limiting the telephone rates. The Court held, however, that this had nothing to do with the case, and did not furnish any excuse or defence for further infringement; and the Cushman Company have now been ordered to cease and close up. This incident has served to call attention to the fact that the fight which has waged for a long time in Indiana over telephone rates has not yet come to an end. The Central Union Company, the licensees of the parent company, has just been engaged in removing some of its poles and wires at Anderson, Indiana, and the reports from various other places in the State show that the present system, which was forced upon the company, has greatly reduced the number of subscribers. At Lafayette,

Digitized by Google

where about 300 instruments were in use, the number has fallen to less than 100, virtually depriving the service of utility and benefit. It is a great pity that this matter cannot be settled in some way, but it may be taken for granted that the telephone people will not be willing to make any concession more than they have done. To yield in Indiana would be dangerous, and would lead to attacks all along the line in pretty well every State in the Union. In Chicago itself at the present time the fight against the telephone company has been quite brisk, but the methods of agitation have been such as to provoke comment, and the law department in the city has been instructed to investigate reports to the effect that money was to exchange hands in the event of the passage by the city council of an ordinance reducing the annual rent of telephones to 75 dollars.

There is a prospect that Boston is to have a comprehensive subway system, not unlike that of New York, but under somewhat different auspices. Permission has just been granted, over the veto of the mayor, to a company to lay conduits on condition of paying to the city all excesses of their profits over 10 per cent. of the capital actually invested, and of allowing the city to run all its own wires through the conduits free of charge. The space to be occupied by each conduit is not to exceed four square feet in cross-section measurement. There has been a great deal of opposition in Boston to this scheme, which practically gives an exclusive franchise, and there is a possibility that it will still prove a bone of contention.

An interesting paper was read last week before the Boston Electric Club by Mr. T. W. Sprague on the subject of "The Application of Electricity to Mining." The Paper does not contain any facts or data that are new, but presents an interesting summary of the progress made in this field, showing some very marked and encouraging results. Mr. Sprague says that the mining business is waiting with open arms for electrical power, and that the motor must conform itself to the essential conditions before anything like success can be attained; and in illustration of this point he mentions a case of which he heard recently. A mining man sent dimensions, &c., of a level to a leading power company, asking for figures, size, cost, &c., of a motor car to draw certain loads in a tunnel. When the reply came back it was found that the motor car would occupy an entire section of the tunnel; but the power wanted was not excessive, and the proper amount of attention would unquestionably soon adapt the car to the work, and make its use feasible.

A special cable despatch in the papers this week from England announces the fact that Mr. George Westinghouse has been awarded the contract for a plant to light the City of London, to cost about $300,000. There is not much news to be obtained on the subject this week; but it is understood from the Westinghouse Company here that this order for their apparatus comes from the company lately organised by Sir John Pender, and that a portion of the apparatus is already on the ground. We are naturally very much pleased to see that American apparatus once more comes to the front, and is approved in a country like England, where judgment in such matters is so good, and where the requirements are generally considered to be so exacting.

That enterprising paper, the *New York World*, has given a striking example of the use to which the telegraph may be put in gratifying public curiosity. A series of base-ball games has been going on to decide the championship of the world, and in order to make the result known as quickly as possible the *World* erected outside its office a huge blackboard on which was drawn a sketch of the baseball ground, or "diamond," as it is technically called. Each of the two "nines" had its own colour, and each of the players of the "nine" had a numbered peg. As soon as the game started at the ground it started also on the board, one side being shown at the bat, and the other side fielding. As each run was made, so the player was moved from base to base on the board, and this was kept up until the end of the game was reached. In order that no time should be lost, a special wire was run from the ground, whether in New York, Brooklyn, Philadelphia, or St. Louis, direct to the foot of the board, where sat an operator, who, as fast as the message was sent in, dictated it to his assistant, who, in turn, made the movements on the board. In this way the spectators could follow every movement of a game being played 1,500 miles away almost as quickly as if they were on the ground itself. The public "caught on," as we say here, and every afternoon while the series of games lasted the board was surrounded by a howling crowd of thousands of enthusiasts, who cheered or groaned themselves hoarse as they followed the movements of those little pegs from hole to hole. This enterprise must have cost a large sum of money, but it paid for itself many times over in the advertising that it gave the paper.

NOTES FROM BRUSSELS.

(FROM OUR CORRESPONDENT.)

BRUSSELS, *November* 12, 1888.

The following is the full list of the awards made by the jury of the Brussels Exhibition: — Diplômes d'Honneur: The Anglo-American Brush Corporation, J. M. E. Baudot, Bouckaert and Co., Schuckert, De Khotinsky, Ganz and Co., Mourlon and Co., H. Pieper, Gaston Planté, Th. Schubart and Kornwuller, Société Anonyme l'Électrique, Société Anonyme du Phœnix, Société Industrielle d'Electricité, the Thomson-Houston International Electric Company, the Postal Telegraph Department (Belgium). Gold medals: J. Berliner, Conradty, Connoy, De Jongh, the Electrical Power Storage Company, A. and V. Flamache, Garbe, Lahmeyer and Co., Léon Hen and Co., Lacombe and Co., Ch. Mildé and Co., V. Reclus, Rickez and Co., Schorch, Société pour l'Exploitation des Cables Électriques (Switzerland), the Thomson Electric Welding Company.—Silver Medals: Boone-Carette, Ed. Buels, Chateau et Fils, Camilaff (Russia), Cass, Shaffers and William (United States), J. B. de Koker, F. A. Hesse, Konioff (Russia), Mathis-Boveroulle, Poege, Eugene Raikem, Van de Plancke Frères, G. van Herzeele, Zwarg, Walput. — Bronze Medals: C. Belot, G. Cheriot, De Chimkewitch (Russia), De Smit, Ehlis Peter, Einhart, Francotte, Hauman-Devos, C. J. Hoffmann, Roubanowitch (Russia), P. Schwenke, J. Tollebeeke.—Diplômes d'Encouragement: Cassart, De Fernelmont, De Backer, D. Kunhardt, J. Redouté, Tossens and Boonroy, Van Bunnen Frères. As announced in your last issue, the jury have thought fit to confer the highest award in their power on each firm which took part in the electric lighting of the buildings and grounds. This wholesale method of reward has naturally been much commented on here; for whatever the merits of the various systems, they were not all equally meritorious. Not only has every vestige of the competitive principle been thus destroyed, but a unique opportunity has been missed, for rarely have so many different systems of electric lighting been working side by side. M. Bandsept had a right to expect a better result from his months of labour and anxiety, and I can hardly think that even the recipients of these valuable *diplômes d'honneur* can be altogether satisfied with this strange award.

The other evening the King, accompanied by M. Vandenpeereboom, Minister of the Railway, Postal, and Telegraph Department, was present at the inauguration of the new electric light installation at the Gare du Nord. The station is lit for the present by 19 2,000 candle-power arcs and 30 750 candle-power arcs, but it is intended later on to extend the installation and greatly increase the number of lamps. One of the things insisted upon by the authorities was that matters should be arranged so as to permit of the lamps being turned on or off as desired, and their brilliancy diminished if necessary. To attain this end, all the conductors have been brought to four central points, where switches control the lamps, the light of which can be lowered, or groups of which can be turned out, the lamps having been arranged with this view in sections of five. The new light, in addition to its other advantages, will be more economical than its dispossessed rival. In spite of the important reductions made by the gas company, who supplied gas to the station at 9 centimes the cubic metre (2s. 1d. the thousand cubic feet), the annual cost of gas was 54,000fr. Now the highest estimate for the electric light is 30,000fr. As the first cost of the present installation is only 51,000fr., the authorities will recoup themselves in two years' time.

In the Grand Duchy of Luxembourg commendable enterprise is being shown in extending the use of the telephone and the electric light. The towns of Luxembourg and Arlon will shortly be connected by a telephone line, whilst Luxembourg, Echternach and Esch are all well provided with the electric light. I anticipate that before long all the *chiefs lieux de canton* will possess central lighting stations.

CORRESPONDENCE.

ELECTRICAL THEORY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: A query put by Prof. Lodge on page 830 of your issue of November 2 appears to me to strike deeply into the heart of the matters now in debate. Writing (in reply to Prof. Poynting) concerning Sir Wm. Thomson's views, he asks:—"Is it not that, finding that displacement currents have no magnetic effect, therefore he ignores them? But then, *have they no magnetic effect?*" (The italics are mine.)

Let us first be quite clear what the language of the query means. Is Prof. Lodge using the term "displacement current" in the strict Maxwellian sense for that which goes on in a stationary dielectric medium (whether homogeneous or not) during the time that an electric displacement is undergoing change in its value? Or does he use the term in any wider sense, including, for example, the case of the mechanical motion of an electrostatically charged body in a dielectric medium? For the latter the term "convexion current" would appear to be preferable.

It may be useful here to refer to Maxwell's views on the matter; doubtless they are familiar both to Prof. Lodge and to Prof. Poynting, and they leave no room for ambiguity.

"The variations of electric displacement evidently constitute electric currents. These currents, however, can only exist during the variation of the displacement" (Maxwell, Art. 60). "Whatever electricity may be, and whatever we may understand by the movement of electricity, the phenomenon which we have called electric displacement is a movement of electricity in the same sense as the transference of a definite quantity of electricity through a wire is a movement of electricity, the only difference being that in the dielectric there is a force which we have called electric elasticity, which acts against the electric displacement, and forces the electricity back when the electromotive force is removed" (Art. 66). "Any increase of this displacement is equivalent, during the time of increase, to a current of positive electricity, from within outwards [referring to case of a Leyden jar, of which the inner coating is charged positively], and any diminution of the displacement is equivalent to a current in the opposite direction" (Art. 111). "We have reason for believing that even when there is no proper conduction, but merely a variation of electric displacement, as in the glass of a Leyden jar during charge or discharge, the magnetic effect of the electric movement is precisely the same" (Art. 499). "We have very little experimental evidence relating to the direct electromagnetic action of currents due to the variation of electric displacement in dielectrics, but the extreme difficulty of reconciling the laws of electromagnetism with the existence of electric currents which are not closed is one reason among many why we must admit the existence of transient currents due to the variation of displacement" (Art. 607). "One of the chief peculiarities of this treatise is the doctrine which it asserts, that the true electric current, that on which the electromagnetic phenomena depend, is not the same thing as the current of conduction, but that the time-variation of the electric displacement must be taken into account in estimating the total movement of electricity" (Art. 610).

Turning now to the case of the so-called convexion currents, it is interesting to note the explicit views both of Faraday and of Maxwell. Faraday says:—"If two balls, A and B, be electrified in opposite states and held within each other's influence, the moment they move towards each other a current, or those effects which are understood by the word current, will be produced." . . . "So, if a ball be electrified positively in the middle of a room, and be then moved in any direction, effects will be produced as if a *current* in the same direction (to use the conventional mode of expression) had existed" (*Exp. Researches*, Art. 1,643-4). Maxwell expands this notion, which he propounds first in relation to electrolysis in Art. 238, then in relation to a stream of electrified metal filings in Art. 248; and, finally, in Art. 770, says:—"If the electric surface-density and the velocity can be made so great that the magnetic force is a measurable quantity we may, at least, verify our supposition that *a moving electrified body is equivalent to an electric current.*' . . . "The electrified surface may be that of a non-conducting disc revolving in the plane of the magnetic meridian, and the magnet may be placed close to the ascending or descending portion of the disc, and protected from its electrostatic action by a screen of metal. *I am not aware that this experiment has been hitherto attempted.*" (The italics are mine.) If I am not mistaken, Maxwell was by no means definitively satisfied on this point; his equations for the mechanical force in the electromagnetic field do not contain an explicit term for convexion currents; such a term was proposed to be added to them by Prof. FitzGerald at the Southport Meeting of the British Association in 1883. But prior to this Prof. Rowland had made, in Helmholtz's laboratory at Berlin, an experiment almost identical with that suggested as crucial by Maxwell. Rowland's apparatus, which he described in the *American Journal of Science and Arts*, in 1878, consisted of a gilt ebonite disc rotating about a vertical axis with a speed of 3,660 revolutions per minute. Though there can be no question of the *bonâ fides* of Prof. Rowland, or of the significance of the numerical results obtained, it would seem desirable that so important an experiment should be repeated by other investigators, the more so as Dr. Lecher, of Vienna, entirely failed with recent apparatus to obtain the same result. On the other hand, Prof. Röntgen, using a non-gilt ebonite disc, was successful in a qualitative repetition. In these experiments an electromagnetic effect was produced by charges of electricity moving in their own plane; but this case is clearly distinct from that of an electrified ball which is being translated along a linear path. In Profs. Ayrton and Perry's well-known theory of the origin of the earth's magnetism, it is assumed that an electrified spheroid rotating on its axis exercises magnetic actions in the space interior to the charges. But in the case of the rotation of an electrified disc or spheroid about its own axis of figure, there is not produced any change of the electric displacement in the surrounding dielectric, whereas in the case of the translation of a charged ball along a linear path, there is a continuous change going on in the displacement at every point of the surrounding medium; that is to say, the translation of the charge is accompanied by displacement currents over and above its action as a mere convexion current. It would seem that what is now wanted is some direct experimental evidence whether displacement currents, apart from convexion currents, produce any electromagnetic effects. Such experiments, though possibly delicate, ought not to be impracticable.

There is, however, a third case that is not touched upon directly by Maxwell, and may possibly be included in Prof. Lodge's query. If a non-homogeneous dielectric which is under influence, and across which there exists, therefore, a certain amount of electric displacement, is internally disturbed, there will be local internal variations in the displacement from point to point, and yet there will not necessarily be any change in the total displacement between the two limiting surfaces. For example, suppose a condenser made of two large equal flat metal plates as the limiting surfaces, with a plate of glass or mica occupying only a fraction of the space between them, the rest of the space being occupied by air. The capacity of the condenser (neglecting edge effects) will be the same whether the solid plate rests against one of the two metal coatings or against the other, or occupies an intermediate position. Yet if, after the condenser is charged, the solid portion of the dielectric is moved across the gap, the value of the displacement at points within the gap will be completely changed. The question then may arise, have such local changes in a non-homogeneous dielectric a corresponding magnetic action? I do not think that there exists any experimental evidence on this point, unless the experiments of Prof. Röntgen (who rotated an ebonite disc in its own plane whilst it acted as the dielectric of a condenser), in the October number of Wiedemann's *Annalen*, are taken as establishing the existence of such an action. If his ebonite disc were homogeneous in itself it is difficult to see what the experiments prove.

The foregoing was written before I read Mr. O. Heaviside's letter, and the extract from Sir W. Thomson's, in *The Electrician* for November 9. Sir William asks us to consider the action of an electrified globe executing a simple-harmonic motion over a finite line. Here there are convexion currents and dis-

Digitized by Google

placement currents, too. Is it to these jointly, or to either of them singly, that we are to look for the origin of the electromagnetic waves? (I notice, by the way, that on line 23 from the bottom of p. 23 Mr. Heaviside uses the word "displacement" in the kinematic and not in the electric Maxwellian sense.) The question, what is the velocity of propagation of vector-potential, is surely not more important than the question whether either, or both, of the actions discriminated above are concerned in the propagation of vector-potential. Will Prof. Lodge let us know how he views the matter?—Yours, &c.,

November 10, 1888. SILVANUS P. THOMPSON.

THE PIEZOMETER FOR DEEP-SEA TEMPERATURE SOUNDINGS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the important Paper read before the Society of Telegraph Engineers last week by Mr. W. Lant Carpenter, an allusion was made when dealing with instruments used to determine the temperature of the ocean, to the weak point in the ordinary thermometer—the fact that this instrument only registers maxima and minima temperatures, and need not necessarily record the temperature at the lowest depth to which it is lowered.

An instrument has been devised by Mr. J. G. Buchanan, F.R.S., called the Mercury Piezometer, which gets over this difficulty, and as it is but little known and has been very successfully used on recent Norwegian deep-sea expeditions, I venture to think that a brief description may be of interest.

The piezometer is nothing more than a Six thermometer with one end open. Its form is that of a ∩-shaped tube, having a large bulb at one end filled with mercury, while the other dips into a mercury cup which is so fitted that, while no mercury can escape, it is open to effects of pressure. The tube is filled with water, and contains a steel index, held in position by a horse-hair spring, just as in the registering thermometer.

The quantity of mercury is so much greater than that of water, and its compressibility so small, that the instrument is far more affected by temperature than by pressure; in fact, an increase of depth of 430 fathoms has the same effect as a fall of 1° C. in temperature. The necessary correction for pressure is obtained from the depth to which the instrument is lowered, as given by the sounding wire. It will be seen that so long as the temperature of the sea does not *increase* with the depth at a greater rate than 1°C. per 430 fathoms, the instrument will record the temperature at the greatest depth to which it is lowered correctly.

The only other instrument which pretends to do this is the capsizing thermometer of Negretti and Zambra, which has disadvantages when used at considerable depths.

A full description of the mercury piezometer is to be found in the *Journal* of the Chemical Society for October, 1878, and also in the "Challenger" Expedition report.—Yours, &c.,

November 12th, 1888. EDWARD STALLIBRASS.

MR. HAROLD BROWN ON ALTERNATING CURRENTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I trust that, as the facts in the case come to your notice, you will modify your opinion on the dog-killing experiments. The large alternating-current installations in this country are a disgrace to electrical engineering; the insulation of the primary wires is absurdly poor, and, in consequence, fires and deaths are of frequent occurrence, as I shall soon have occasion to prove publicly. Tests have been made in a number of installations which show that on damp nights the leakage to ground is sufficient to kill any person touching either primary wire while standing on a wet place. The line work is in many cases carelessly done, and frequently the converters are placed indoors and within reaching distance of gas and water pipes. When you consider what a network of telephone and telegraph wires exists in the streets of every American city, you can get some idea of the danger to life which is thus caused, and which is intensified by the declarations of the alternating-current company employés that their systems are "absolutely safe" and "perfectly harmless," for samples of which I refer you to the reprints in the *Electrical World* of July 28. Against such misrepresentations the only effective answer was to use their own current and find the lowest voltage producing death, comparing it with the effects of the continuous current. This, with the kind assistance of Mr. A. E. Kennelly, I did, and the results proved that less than 200 volts of the alternating current was fatal, while, when the extra current caused by opening the circuit was eliminated, the continuous current was harmless at 1,560 volts, which was the highest then at command. I inclose a report of experiments under the auspices of Dr. Cyrus Edison and Dr. Chas. F. Roberts, of the New York Board of Health, and call your attention to the fact that Dr. Frederick Peterson is considered high authority on nerve structure, and Dr. Frank H. Ingram is an expert on diseases of the brain, while all the physicians present have had extensive experience in vivisection. Therefore, their opinion that "a dog has a higher vitality than a man, and that, therefore, a current which killed a dog would be fatal to a man under the same conditions," is entitled to careful consideration. I trust that in the spirit of fair-play for which the English people are famous you will give me space in your columns to endeavour to correct the impression that I wantonly sacrificed the lives of animals. The present tendency of electrical manufacturers and lighting companies in this country is toward higher and higher potentials; it is becoming common practice to run eighty to one hundred or more arc lights on a single circle circuit, and alternating currents of twenty-five hundred volts and more are being introduced. This upon wires whose insulation resistance is so low that heavy leakage can be detected even in dry weather. The list of fatal accidents in the United States already runs into the hundreds, nearly all of which are due to this criminal carelessness and false economy, and I intend to keep at work until legislation has placed all possible safeguards around the use of dangerous currents. A telegram from Pittsburg in yesterday's newspapers states that "George Westinghouse's Electric Company has been awarded the contract for a plant to light the City of London, England, to cost about $300,000." If this is true, you will be enabled to judge of the merits and "economy" of this type of apparatus, and I venture to say that you will not be overcome with enthusiasm. If it is untrue, you will be able to judge of the character of the people against whose reckless claims and careless methods I have been contending.—Yours, &c., HAROLD P. BROWN.

New York, November 1, 1888.

[We would refer our correspondent to a note in our editorial columns.—ED. *E.*]

The following is the extract enclosed with Mr. Brown's letter:—

At the School of Mines of Columbia College, experiments were lately undertaken, at the request of Harold P. Brown, electrical engineer, to determine the danger of alternating currents, by Dr. Cyrus Edson and Dr. Chas. F. Roberts, of the New York Board of Health. The first dog operated upon was a mongrel, weighing 61lb., strong and in good condition. His height was 24in.; length, from tip of nose to base of tail, 42in.; and resistance, from the right front leg to the left hind leg, 14,000 ohms. Connection was made by binding a piece of cotton waste saturated with water round the leg with No. 20 bare copper wire. The dog was placed in the cage and the alternating current applied by Dr. Roberts at 272·16 volts for five seconds; number of alternations, 288 per second. The dog was silent and motionless during the continuance of the current. He gave a few spasmodic gasps 31 seconds after current was first applied, and heart ceased beating 90 seconds after current was applied. The dog was immediately dissected by Dr. Roberts and Dr. Peterson, and section of sciatic and pneumogastric nerves, muscular fibres of diaphragm and lungs, placed under a microscope, and no changes in structure were observed. The second dog was a full-blooded Newfoundland, strong and in good condition, weighing 91lb.; length, from tip of nose to base of tail, 48in.; height, 25in.; resistance, 8,000 ohms. Connection was made in the same manner as above. Alternating current applied by Dr. Roberts at 340·5 volts electromotive force for five seconds. The dog was silent and motionless during continuance of current; howled and gasped for eight seconds after circuit was opened, but in the opinion of physicians present this was purely mechanical action, as the dog was unconscious from the instant the current first reached him. Heart stopped beating in two minutes and fifty seconds after current was first applied. The third dog was a half-breed setter and Newfoundland, weighing 53lb., 42in. long from tip of nose to base of tail, and 24in. high; resistance, 30,000 ohms. Connections were made in the same way as before. Dr. Roberts applied the alternating current at 220 volts for five seconds; the result was not fatal at four minutes afterwards. Mr. Porter, superintendent of machinery of Columbia College, then suggested that as the dog was rigid and motionless during the continuance of the shock, it would be impossible for a man in the same conditions to utter a sound or to break the contact in five seconds. Dr. Edson then determined to administer the current at the same number of

Digitized by Google

volts for 30 seconds on this account and on account of the high resistance of this subject. This was done, and during the period of the 30 seconds the voltage rose to 234 volts. The dog died instantly without sound or struggle. The resistance after death was found to be 2,800 ohms. All of the physicians present expressed the opinion that a dog had a higher vitality than a man, and that, therefore, a current which killed a dog would be fatal to a man under the same conditions. It was their opinion that all of these deaths were painless, as the nerves were probably destroyed in less time than that required to transmit the impression to the brain of the subject.

Dr. Edson invited Elihu Thomson, of Boston, and Dr. Otto A. Moses to be present with measuring instruments to check up the voltage, &c., but neither of these gentlemen put in an appearance or responded. Approved by Dr. Cyrus Edson, of the Board of Health; Dr. Chas. F. Roberts, Assistant Professor of Physiology, Bellevue Hospital Medical College; Dr. Frederick Peterson, Dr. Frank H. Ingram, Dr. H. A. Haubold, Mr. John Murray Mitchell, Professors C. E. Colby and E. H. Laudy, of Columbia College; Captain E. L. Zalinski, U.S.A.; and Dr. Schuyler S. Wheeler, Electrician of the Board of Electrical Control.

GLOBE LIGHTNING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I think the following account of what appears to be an instance of globular discharge may be of interest:—

On the 18th of last April a line foreman, formerly in the Royal Engineers, and whose veracity does not admit of doubt, was standing in the terminal room of the United Telephone Company's exchange at Westminster, the window facing north being wide open, when he saw an ordinary flash of lightning; this was accompanied by a crash of thunder, almost explosive in its violence and lasting for several seconds. Immediately the sound had ceased he saw what he describes as a fiery ball, about an inch in diameter, resembling a mass of white-hot iron enter the window with a fizzing noise—like a fuse burning or a rocket rushing through the air—and leaving behind it a fiery trail; it struck against the terminal board with a thud, as though the ball were of some plastic material, and then bounded back again out of the window. A slight odour of sulphurous nature was noticed. No mark was left on the board, but about thirty indicators were found to be damaged in the exchange.—Yours, &c.,

C. H. WORDINGHAM, A.K.C., A.S.T.E.

[This seems to be one of the most remarkable cases on record. Can our correspondent describe the nature of the damage sustained by the indicators? Were the coils burnt or fused as from a powerful current, or were the metal frames damaged?—ED. *E.*]

TELEGRAPHY WITHOUT WIRES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The extent of the field in which return currents may be "picked up" by intermediate conductors, in the manner shown by Mr. Willoughby Smith, is a subject deserving more research than has hitherto been given to it. Mr. Swinton, in his letter of last week, gives his experience in this direction, and it is by no means an uncommon one to those engaged in working telephone circuits in large towns; in fact, such currents have, in some instances, at times been of sufficient strength to work the indicators in exchanges. The principal offenders in this respect are the printing telegraph and the Wheatstone automatic circuits, the latter, owing to the rapidity of its makes and breaks and current reversals, being the most noisy. One of the most remarkable instances that I have experienced was on a circuit inside a building in London. The line, which was not more than 40 yards long, was an insulated copper wire, and ran between two rooms on the fourth floor, one in the front and the other in the back of the building. The gas pipes were used as the return. On this circuit the humming of the Wheatstone automatic instrument could be distinctly heard in a telephone, and the periods when the machine was running empty or with messages clearly distinguished. No telegraph wires were anywhere near overhead the nearest underground ones running parallel to the direction of the line were about 200 yards away, and some were probably under the street in which the building stood, and would then be at right angles to the direction of the line. The only explanation I could arrive at was that as the gas supply for the front rooms of the building was brought by a pipe in the front portion, and that for the back room by a pipe in the back, these two pipes may have earthed in two different points, and so picked up a current. The fact that the whole supply of the building was from one meter in the front would appear to be against this solution to some extent; but if this were the correct one it shows how remarkably easily these currents may be "picked up."

In those cases where the noise from the picked-up current prevents the proper working of a telephone, or if the current is of sufficient strength to operate the indicator, the trouble has generally been overcome by obtaining a new earth for the telephone, as far from that of the offending telegraph instrument as possible. Sometimes, when several telephones have earthed near a telegraph earth, it has been necessary to run one low-resistance wire from some good earth, or from the exchange, and use this for the earth of all these telephones. In America, according to a Paper read before the Telephone Congress, the same difficulty has been found and cured in a similar manner, only in their case electric railway currents seem to have been the chief cause of the trouble.

I am afraid that the term induction is often used in this country to cover a multitude of sins. The American phrase cross-talk is better, as it covers induction proper, leakage and picked up currents.—Yours, &c.,

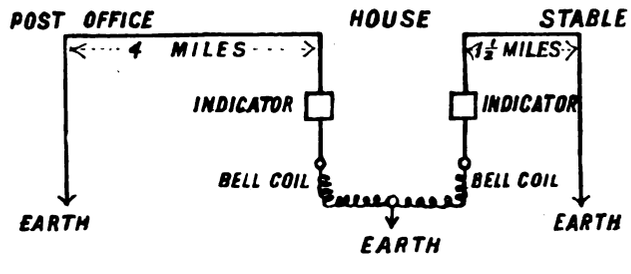
F. B. O. HAWES.

East Ferry-road Engineering Works,
14th November, 1888.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: With reference to this subject the following facts may be of interest to your readers:—

Some ten or twelve years ago, when living in Northamptonshire, I had an A B C Wheatstone instrument in my house, in communication with the Stamford post office, distant about four miles. I had also a line to some stables about one and a-half mile in an almost diametrically opposite direction. The two lines met in the house and were conducted, first through indicators and then through a specially constructed bell, with separate coils for each circuit to earth. The earth was made as good as possible, nevertheless it was frequently found that on one station endeavouring to call me up enough current returned through the other line to work the indicator and bell at far end, so that both indicators would drop, and the man at the stables, say, thinking I was calling from the house, would endeavour to reply; and it was not until I inserted a very considerable resistance in each line that I could stop this effect. I cannot at the time recall what the necessary resistance was, but I believe I have the coils somewhere, and if you think it would be of interest I will endeavour to ascertain their resistances. The following rough sketch may help explanation:—



Of course in using the arrangement the line in use was switched off the indicator on to an A B C instrument, one instrument thus serving for either line.—Yours, &c.,

R. H. C. NEVILE.

Wellingore Hall, Grantham, November 12, 1888.

[Does not this merely go to show that the "earth" was bad at the house, or at any rate that it had a much higher resistance than that at either end of the line?—ED. *E.*]

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have much pleasure in replying to Mr. Charles Bright's inquiries on the subject of my experiments for telegraphing without wires. The boat employed on this occasion was a

Digitized by Google

wooden one, but it would have been much better for my purpose had it been of metal, for then I should have used it in the stead of one of the accumulating plates, as the larger the surface of these plates the better the results obtained.

With regard to the position of the plates, of course there would be a difference, for as I say in my letter, when speaking of the tank experiments, "These two wires, so fixed and immersed, were moved in each section, until the position of maximum potential was obtained." But there are many ways of obviating this difficulty in a shifting body.

In my experiment from the beach the plates are drawn as hanging perpendicularly from the boat, but considering the force of the current and the boisterous state of the sea, which caused the boat to be very unsteady, it would be difficult to say what was really the position of the accumulating plates.

Electrical signals were sent from the shore to the boat, and also from the boat to the shore, the rapidity and correctness with which they were received more than realising my expectations.—Yours, &c., WILLOUGHBY SMITH.

November 12, 1888.

MR. CAMPBELL SWINTON'S "PHENOMENON."

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The disturbance upon a wire between 75, Queen Victoria-street and 59, Knightrider-street, mentioned in Mr. Swinton's letter in your last issue, is, I think, more likely to be due to induction from a wire of ours which crosses it than to the cause mentioned. Our signals upon that wire resemble those of the Wheatstone, and are sometimes audible in telephones.—Yours, &c., F. HIGGINS.

17 and 18, Cornhill, E.C., November 9, 1888.

TELEPHONE CALL OFFICES IN LONDON.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In giving 1880 as the date of the first London Call Office, Mr. Munro is basing on information that *must* be inaccurate. It is a matter of common knowledge in telephone circles that there was no call office in London prior to 1883. In order to make good his assertion Mr. Munro should give the exact addresses of the call offices he refers to, and mention the date of the first list of subscribers issued by the United Telephone Company in which the opening of a call office is announced. If he will look into the matter for himself he will find that 1883 is the real date.—Yours, &c., A. S. T. E. and E.

November 12, 1888.

REWARDS FOR MERITORIOUS DISCOVERIES AND INVENTIONS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The Committee on Science and the Arts of the Franklin Institute, of the State of Pennsylvania, respectfully requests that you will cause to be made known to the readers of your influential journal the fact that the committee is empowered to award, or to recommend the award of, certain medals for meritorious discoveries and inventions which tend to the progress of the arts and manufactures.

These medals are:—

1. THE ELLIOTT CRESSON MEDAL (GOLD).—This medal was founded by the legacy of Elliott Cresson, of Philadelphia, and conveyed to trustees of the Franklin Institute. By the Act of the Institution, May 17, 1849, the Committee on Science and the Arts was designated and empowered to award this medal, and the committee decided to grant it, after proper investigation and report by sub-committee, either for some discovery in the arts and sciences, or for the invention or improvement of some useful machine, or for some new process, or combination of materials in manufactures, or for ingenuity, skill, or perfection in workmanship.

2. THE JOHN SCOTT LEGACY PREMIUM AND MEDAL (20 DOLLARS AND A MEDAL OF COPPER).—The John Scott Legacy Premium and Medal was founded in 1816 by John Scott, a merchant of Edinburgh, Scotland, who bequeathed to the City of Philadelphia a considerable sum of money, the interest of which should be devoted to rewarding ingenious men and women who make useful inventions. The premium is not to exceed 20 dollars, and the medal is to be of copper, and inscribed "*To the most deserving.*"

The control of the Scott Legacy Premium and Medal (by Act of 1869) was transferred to the Board of Directors of City Trusts, and referred by the Board to its Committee on Minor Trusts, and that committee resolved that it would receive favourably the name of any person whom the Franklin Institute may from time to time report to the Committee on Minor Trusts as worthy to receive the Scott Legacy Premium and Medal.

The Franklin Institute, by resolution in 1882, accepted the above-named action of the Committee on Minor Trusts, and referred the duty of making such recommendations to the Committee on Science and the Arts. The committee determined that the recommendation for such reward shall be made on the favourable report of a sub-committee which shall be appointed to examine the invention or discovery.

The committee requests your co-operation in facilitating the making of the aforesaid award for meritorious discoveries and inventions by bringing the facts herein set forth to the knowledge of your readers.

Upon request therefore, from interested parties, made to the Secretary of the Franklin Instititute, full information will be sent respecting the manner of making application for the investigation of inventions and discoveries; furthermore, the Committee on Science and Arts will receive and give respectful consideration to reports upon discoveries and inventions, which may be sent to it with the view of receiving one or the other of the awards herein-named, and full directions as to the manner and form in which such communications should properly be made will be sent on application.—By the Committee's order,

WM. H. WAHL, Secretary.

The Franklin Institute of the State of Pennsylvania
for the Promotion of the Mechanic Arts,
Philadelphia, October 1st, 1888.

ELECTRIC LIGHT AT THE BANK OF ENGLAND.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: As we hear that a report has been circulated in the City with reference to the above installation which may be prejudicial to electric lighting interests, we shall be glad if you can find space for a short explanation of the facts.

We are pleased to say there is not the slightest foundation for the statement that the Bank of England are discontinuing the use of the electric light, in fact we are at this moment engaged in fixing two large gas engines to supplement the 50 horse-power steam engine, which has run without a hitch of any kind from the moment it was started. Possibly the rumour has originated through the temporary cessation of the light in the drawing office, where it had been found necessary to rearrange the early installation put down by another company some years ago. But we shall have this ready for use again shortly, and in the meantime we are pleased to notice that the short compulsory return to gas is by no means appreciated by the bank staff.—Yours, &c.,

DRAKE AND GORHAM, Electrical Engineers.

Digitized by Google

As most of our readers will be aware, the Telephone Construction and Maintenance Company, whilst manufacturing the whole of the instruments required by the United Telephone and its subsidiary companies, and also by the Postal Telegraph Department, are precluded from the sale of their instruments in the open market within the limits of the United Kingdom. An outlet for their enterprise still exists, however, in the manufacture and supply of telephone *matériel* of all descriptions for the remainder of the civilised world, and in consequence a very large variety of "combination sets" of transmitting, receiving, and call instruments has been designed to meet the varying needs of their customers. Some of the latest of these we shall briefly describe.

The "Consolidated Magneto Telephone," while being considered a first-class instrument for exchange purposes, is described as being specially suited for use in remote districts, where non-liability to get out of order is a first consideration. We can hardly doubt that this requirement has been adequately fulfilled in the type before us.

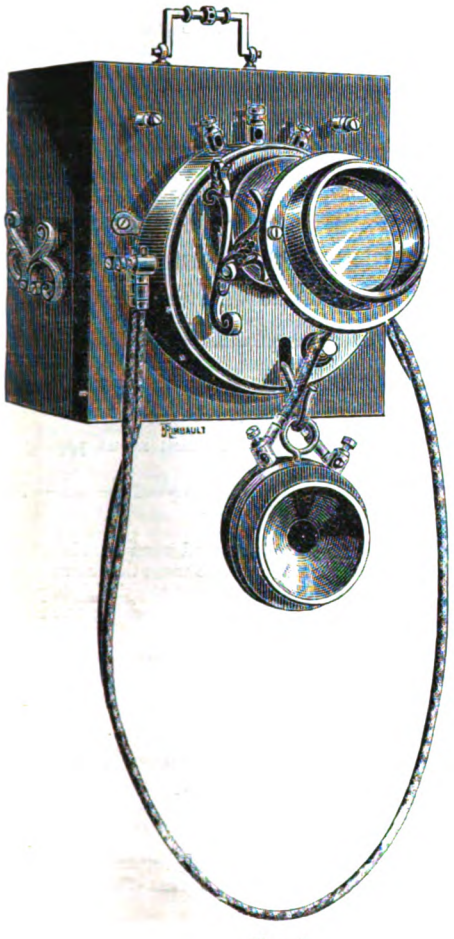

Fig. 6.

The apparatus (Fig. 1) consists of a combination of parts which in the experience of the company have been found most effective in practical use. The transmitter is a modified form of the Crossley type, in which a number of carbon pencils radiate from a central block mounted on a diaphragm, the outer ends of the pencils being held by separate blocks of carbon, which are fastened directly to the framework of the instrument, as shown in Fig. 2. This arrangement is peculiarly sensitive, and requires no adjustment of any kind. The armature of the magneto call transmitter is driven by tooth-geared wheels, which for this purpose are more reliable than friction gear. The receiver is of the ordinary Bell type. Fig. 3 illustrates a set of the same general description, but adapted for standing on a desk or table. The call bell is at the back. Fig. 4 illustrates a form which is specially designed for the sake of simplicity and cheapness. Three Leclanché cells, not shown in the figure, are required for the transmitter and call bell. Fig. 5 is a still less expensive type, and is intended chiefly for use in large establishments or for private lines. Fig. 6 is a neat portable arrangement known as the "FitzGerald" combination. It is particularly adapted for offices that require to be connected up from floor to floor, and the company have invented and patented a very cheap form of switchboard to be used in connection with this instrument. Fig. 7 illustrates a complete set of transmitter and receivers intended to be worn by a diver under his helmet. The receivers cover each ear, whilst the transmitter is fitted in a recess near the mouth. Fig. 8 illustrates the arrangement at the shore end of the diver's telephone, at which a battery transmitter is employed. A large number of these sets have been supplied to the Admiralty, and have been used with great success Fig. 9 represents the "Operator's telephone," as used by the General Post Office in some of their exchanges. It consists of a transmitter (*a*), receiver (*b*), and closing key (*c*) contained in the handle by which it is held. Fig. 10 represents an "Operator's receiver," which is worn strapped upon the head. This form is largely used in Lisbon by subscribers to the exchanges who wish to hear the opera from their own houses.

Numerous other forms are made by the Consolidated Telephone Company, embodying the Blake and Hunnings transmitter and the Gower-Bell receiver; but most of these combinations, except for special purposes, are of less value than those described.

COMPANIES' MEETINGS.

West India and Panama Telegraph Company (Limited).

The twenty-third ordinary general meeting of this Company was held at Winchester House, Old Broad-street, on the 14th inst., under the presidency of Mr. C. W. Earle.

The SECRETARY (Mr. R. T. Brown) read the notice calling the meeting and the minutes of the last general meeting, which were confirmed and signed by the Chairman as correct. The report of the Directors was taken as read.

The CHAIRMAN: Gentlemen, our meeting to-day is marked by one circumstance which makes it of a somewhat exceptional character. It is the first time in the twenty years since the Company has been in existence that we have ever met with all of our cables in working

Digitized by Google

order. You see by the map that there are a great many separate sections. They are not all ours, but the map shows what a number of sections we have, and we are very subject in that unpropitious field, the Caribbean Sea, to interruptions. I do not wish you to draw too favourable an augury from this absence of interruptions. Though I believe the system is in a stronger and better condition than it ever was in before, still, knowing what I do of those waters, I do not wish to lead you to suppose that the halcyon days of freedom of disasters which are so costly to us are likely to arise. In fact, I may tell you that since this report was written we have had one interruption. It was, fortunately, smartly repaired by our maintenance ship, "The Duchess of Marlborough," and it was of very short duration. I merely mention that to show you that even while we are now speaking the satisfactory condition of things to which I am alluding may be modified. With regard to the accounts, it is satisfactory to note that there is a small increase in the traffic revenue of the Company. On the debit side of the accounts there is very little indeed to remark upon. There is a slight increase in the salaries and wages—a fact accounted for by the promotions that we think it just and politic from time to time to give to the *employés* of the Company whose experience and length of service warrant a little encouragement. A hopeless service would be a bad service, and I think that the few pounds that we lay out in encouraging the staff from time to time and we have to do it with rather close hands, I am sorry to say) is a good policy for the Company. The chief increase in the expenditure side of the accounts is owing to expenses for repairs of cables, which amounted to £2,241 in excess of those of the corresponding period of 1887. That increase is entirely accounted for by the extra length of cable we have been obliged to put in in course of the sundry repairs executed during the half year, but that expenditure is not without its compensating influence upon the accounts, because it goes to diminish the contribution we should otherwise have to make to the reserve fund. Of course the reserve of a telegraph company is principally a depreciation fund—a fund built up for the renewal of the cables from time to time, as they may fail, and if at any one time we may put, say, 100 miles of new cable into the system, that goes towards fulfilling the purposes of a reserve fund, and exonerates us from putting the whole sum which we should otherwise have to do to the reserve fund to keep up the calculated extent of depreciation. With regard to the reserve fund, the policy of forming it at all and of keeping it up has been very often seriously criticised in this room; but I think I may claim that the present market position of the shares of the Company, in comparison with what it was in former days, is very much owing to the existence of that reserve fund which we have, in spite of a good deal of opposition, never ceased to maintain, and I hope this meeting will endorse that policy and encourage the Board to keep up the mainstay of our system and the basis of what little prosperity we may have. Our report this time is, perhaps, the shortest we have ever laid before you; but I should be, perhaps, not properly filling my place here if I led you to suppose that that fact was attributable to there being no clouds on our horizon in the West Indies. There is, I am sorry to say, a growing feeling among the Governments of that region against the continuance of our subsidies. They are now voted only annually. At first these were voted for ten years. Those subsidies then expired, and, in many cases, the Councils and Chambers of the various Governments have taken to voting an annual subsidy only. That is an unfortunate policy, both for them and for us—for us because it gives us no security of tenure, and that absence of security of tenure tends to restrict our operations in carrying out the measures which would be to the benefit of the telegraph service of the country. For instance, there is no encouragement for us to duplicate a weak cable when the subsidies are only the matter of an annual vote. There is also another cause for anxiety about our position in the West Indies; that is, the renewal of the French competition. Since we last met a new cable has been laid by a French Company from Venezuela to San Domingo and Santiago de Cuba. At present that Company does not interfere very seriously with our traffic, and we should not oppose them did we not know that their statutes their articles of association—lay down that one of the objects of the Company is to extend and develop French telegraphs, and we are not without some anticipation that they may eventually make extensions into our territory. I believe the ground they occupy now is in contravention of their own concession, and I am quite sure it is in contravention of our Spanish concession, and we have therefore felt it our duty in protection of your interests to call the attention of the Spanish Government to the subject. We do not want to act the part of the dog-in-the-manger, but we object very strongly to their going to any of our stations. Not one of those stations can afford to support another company, and therefore competition would not only be disastrous to us and to the colonies but also to the competing company. I now beg to move the following resolution:—

"That the Directors' report and accounts to the 30th June, 1888, submitted to this meeting, be and the same are hereby received and adopted, and that, as recommended by the Board, a payment of 12s. per share on account of arrears of dividend on the First Preference Shares be and the same is hereby declared."

Mr. FORD seconded the motion.

Mr. ODELL asked how it was that there had been an increase in the item of insurance of ships.

The CHAIRMAN: There is no increase. It may be the incidence of the insurance that became due just before the accounts were closed, but there is no increase in the insurance charges for the year.

Mr. ODELL: Last year the amount was £522, and this year it was £1,422, so there must be an increase.

The CHAIRMAN: If you take the corresponding account you will find that the amount is the same. The insurances are payable in April. It is merely the incidence of the payment. There is no increase.

Mr. ODELL said that one of their investments was £5,000 in Three and a-Half per Cent. Debenture Bonds of the Oude and Rohilkund Railway, and he stated that there was no such stock in the share list.

The CHAIRMAN: It is not actually quoted; but it was the very best thing that we could buy at the time. It is going to be paid off, I believe.

Mr. FORD: I believe you can get more for it now than it cost you. I am told that there is a daily market for the bonds.

Mr. ODELL said he had carefully calculated the present value of their investments, and found that at the lowest quotations there was a profit of over £11,000. The only investment that showed any loss was the East and West India Debenture Stock, and the Directors had increased their holding in the past half year in that stock.

The CHAIRMAN: We have rounded off the amount of that investment. That stock is very low, and we are told and believe that it will come out right.

Mr. ODELL said that the bonds only stood at 80 now. He thought, seeing that that the arrears of dividend were now reduced to only £44,000, that that amount ought to be paid off out of the investments, and then a dividend of 2 per cent. could be paid on the Ordinary shares and £7,000 could be added to the reserve fund. He had been a shareholder for sixteen years, and during that time he had received only two small dividends.—

A SHAREHOLDER asked whether any communication had taken place between the Company and the Colonial Governments on the subject of their limiting the period for which the subsidies were now paid. Had the Governments given any reason for their action? Was it due to any interruptions of the cable?

The CHAIRMAN: We are in frequent communication with those Governments. It is not owing to interruptions, but in consequence of the idea that prevails that someone else is going to take a cable to their islands, and therefore they do not wish to be bound for any length of time to us. In reply to another question, the Chairman added: The total subsidies received by the Company amount to £24,000 a year if they are all paid, but they make deductions for interruptions and other things.

Mr. WHEELER observed that at the last meeting reference was made to a Company working between Trinidad and the main land, and he believed the Chairman said on that occasion that the Directors were in communication with the Government on the subject.

The CHAIRMAN: I referred to the duplication of the Barbadoes and Demerara cable.

Mr. WHEELER inquired what the result of the communication had been?

The CHAIRMAN: Nothing further has occurred.

Mr. ODELL said he would like a reply to his remark about paying off the arrears of dividend out of the reserve fund.

The CHAIRMAN: It is a very satisfactory account altogether, but you want us to take this money out of the reserve fund.

Mr. ODELL: Well, and why not do so?

The CHAIRMAN: The reserve fund is calculated upon a certain basis to meet the depreciation of our cables, and before we meet the depreciation which occurs in our cables year by year we have not any divisible profit. The reserve fund is for depreciation, and not for division among the shareholders.

Mr. FORD observed that if they were to adopt Mr. Odell's suggestion they would next time have to use the whole of the profit to make up the amount paid away as advocated by Mr. Odell. It was the duty of the Directors to keep up the reserve fund.

Mr. WM. ANDREWS: And the reserve fund must grow as depreciation grows, unless you can stop the depreciation that goes on at the bottom of the sea.

The CHAIRMAN put the motion, which was carried.

On the motion of Mr. NICHOLSON, seconded by Mr. ODELL, a vote of thanks was passed to the Chairman and Directors.

The CHAIRMAN: I am very much obliged to you, and so are the Board, for your vote of thanks. We shall always do what we can to promote the interests of the Company.

The proceedings then terminated.

The Australasian Electric Light, Power and Storage Company (Limited).

The sixth ordinary general meeting of this Company was held at the Company's office, 41, Coleman-street, on Monday last, under the presidency of Mr. B. H. Van Tromp.

The SECRETARY having read the notice calling the meeting,

The CHAIRMAN said: In rising to move the adoption of the report and accounts, I think it will only be necessary to trouble you with a very few observations. You will remember on the last occasion that I told you we had made new arrangements with respect to the expenses in Australia and London. Those new arrangements only came into operation for two months of the year 1887, up to which date these accounts are brought down, and, therefore, it was not apprehended that we should derive much benefit from the changes made, in so far as last year's working was concerned; the benefit will accrue in future years, and has already accrued in the current year. In looking at the accounts now submitted you will find that there has been a loss on the year's working down to the 31st December last. I think it was pretty well understood at the meeting held in October last year that there would be a loss; but I told you then that we had great hopes in the future that we should so keep down expenses as to prevent the possibility of a loss, and I venture to hope that when we meet you this time next year we shall be able to bring

Digitized by Google

before you such a statement of accounts and such a statement of the progress made in Australia as will give you renewed confidence in your Board, and that you will continue to believe, as I feel sure you do at this moment, that we are perfectly honest in our endeavours to do the best we can for this Company. You will remember that at the close of my speech last year, when you were kind enough to pass a resolution of confidence in the Board, I gave a pledge in the name of the Directors that no effort should be wanting on their part to bring this Company eventually into a dividend-paying condition. Our efforts this year have been mainly directed to securing a contract in Melbourne for the lighting of the Exhibition there—a contract larger than has ever been entered into, and an enterprise more important as regards any exhibition of a temporary character in the whole world. When I tell you that this arrangement was carried out solely by means of cablegrams to Australia, requiring daily watchfulness, constant meetings, and the utmost care and attention in giving directions in Australia, so as to secure the contract without the possibility of loss, I think you will see that we have been working hard to promote your interests. Captain Rowan, our able manager in Australia, made supreme efforts to get this contract, and he was successful, being most untiring in his exertions on your behalf, and showing an amount of ability which scarcely anyone on this side had up to that time given him credit for. That contract was secured against a very large number of competitors, American, German and Hungarian. There were others, too, who tried to obtain it, but we succeeded in getting the contract, and, as far as our present advices will enable us to say, we on this side expect to receive a net profit of at least £4,500 or £5,000 out of that contract alone. I think this is something that should be mentioned with a degree of satisfaction by the Board, and I do hope that the shareholders will give us credit for having taken immense trouble and devoted a great deal of time and attention to the securing of such a work. In addition to the profit that we are going to make from it it has given us a high position in Australia, and it has given electric lighting a great start there. The commissioners to the Exhibition have stated that the whole of the work has been carried through to their entire satisfaction, and that the lighting has succeeded in every respect, and we have not received on this side a word of complaint in respect to it. It is a great satisfaction to us to tell you we believe that no penalty will be incurred in connection with the contract. We were ready at the moment, though we had only two months in which to prepare in this country and send out an enormous plant. You may possibly wish to know how that was done without our having any money. From the last accounts you will see that the Company possessed in uncalled capital about £11,000 or £12,000, upon which there was a loan of £5,000, so that all the credit we had was about £6,500, and if we had called up that it would have exhausted all the Company's money. The Board thought it better to act on the advice of a shareholder at the last meeting, who implored us not to make the final call. The Directors, instead of that, gave their personal guarantee, and also entered into a very satisfactory arrangement with the Anglo-American Brush Company to supply the plant. I do not propose to refer at any length to the accounts of 1887, which are before you. You can, as men of business, see where the loss has been; but I will ask your special attention to the items which have been put in comparative columns, and you will see that, except in the item of cables and telegrams, there has been a saving under every heading. But for our care in that respect, the loss made in 1887 would have been very much greater. I told you last year that we were in a sort of transition state in Melbourne. We were having a very voluminous correspondence with Captain Rowan and agents in the colony, and we wanted to reorganise the whole thing. But at this distance from Australia, it is very difficult to carry out any arrangements through correspondence and cablegrams. Everything, therefore, apparently remained at a standstill. In our negotiations with the agents, and in our correspondence with Captain Rowan, the business of the Company over there was to some extent lost sight of. Hence it was that the profits were not so large and the sales were not so great. On the other hand, we have succeeded in doing what I have mentioned, and I believe that the adoption of the electric light in Australia and the whole of the Colonies, at the Cape and in India, is purely a matter of the future. We are the holders of the field there. We have the greater portion of the Cape of Good Hope, India, Queensland and New Zealand. We have all that before us, and I can only tell you this, that there is only one thing wanting to make us a tremendous success in all these places, and that is money. I pointed out last year that before we began work three-fourths of our capital had disappeared, invested in patents, &c. This is the seventh year of the Company's existence, this being our sixth annual meeting, and we have, therefore, served our apprenticeship. We have our indentures in our pockets, and we intend to do something with them in the future, with your assistance. It is my belief, and the opinion is shared by the whole Board, that if we could see our way, by issuing Preference shares with a dividend of 5, 6, or 7 per cent., or whatever you might agree upon, to obtain £15,000 or £20,000, which could be devoted exclusively to the purpose of opening a magnificent lighting station in some large city like Bombay or Calcutta, or at Sydney, Adelaide, and other large towns of Australasia, we should make a very handsome profit on that amount. If we gave our pledge that that money should not be used except for establishing a large lighting station having good prospects of success, I believe that you who are present and those who might be appealed to on a future occasion would give us their hearty support. Upon that matter, however, I will not say any more. There are others here who may say something about it. We court the fullest discussion as to the affairs of the Company. I have always looked upon Directors as the servants of the shareholders, and not as their masters, as some Directors consider themselves. We want your advice. We have a very good thing in this Company, and I believe there is a great future for it in connection with our interests in the Australian Electric Company, which is established in Melbourne. You may remember in the earlier part of our history the establishment of a company in the city of Melbourne, in which we hold an interest representing more than a third of the capital. That company are carrying on a considerable business. Their lighting is extending very considerably. They have made new contracts with large wholesale houses for lighting, and are spreading their work throughout the whole of the city. But they are doing more. They are trying to bring into existence a new body of gentlemen, who will find plenty of money in order to bring this thing thoroughly into effect in the city of Melbourne. I am informed at this moment that negotiations are going on, under which the Australian Electric Company will be, I will not say absorbed, but joined to a larger undertaking with ample resources. You may depend upon it we shall try and get a good *quid pro quo* for our shares in that company. The lighting of the Exhibition, having been such a grand success, has excited the attention of everyone on that side of the world to the importance of the electric light, and we do firmly believe that if you can only wait a year or two more you will be rewarded. If you let us go on for a year or two more I am sanguine that we shall be successful. I think there is nothing that commands success so much as the feeling that you must have success and that you deserve it. In this case we deserve success. The shareholders have shown the utmost patience, and we still look to them for their support, consideration, and assistance. Throughout the whole world there is now a great movement for the electric light. The Edison Company, I see by a paragraph in the newspapers, contemplate increasing their capital. They are putting up a new station in the capital of Berlin, and the cry is still for more light. In the city of Berlin they appear to be determined to have no street lighted except by the electric light, and the day is coming when London, and, indeed, every city in the world, will make use of the electric light, unless a better one can be found. I may say with regard to those dreadful Whitechapel murders, that it is stated that every arc lamp in the streets of New York is equal to one policeman. That is what is said there. As time goes on and the electric light is more easily understood, there will be no diffi-

culty in every citizen of London having the light put into his house, and I venture to predict that there will be no increase in the cost of lighting by electricity as compared with lighting by gas or candle. I am a director of a large hotel, in which we have recently installed the electric light, and we are going to keep it, as it gives immense satisfaction to visitors, and there is little additional cost.

A SHAREHOLDER: Is it your own installation.

The CHAIRMAN: Not at present. We have a contract; but by next year we hope to make it our own installation. I need not dwell upon the advantages of the electric light, as they are so well known and recognised. I can only point out the immense safety of the light. Look at the number of deaths that occur through the use of lamps, and remember that the moment the electric light ceases to burn, or the moment the air gets to it, the light goes out.

A SHAREHOLDER inquired what was the hotel to which the Chairman had referred.

The CHAIRMAN: The Grand Hotel, Brighton. Last year I was at the Schweitzerhof Hotel at Lucerne. There, in the bed rooms, lavatories, and other places open to visitors and the public, the electric light was in use. You turned it on as you entered a room and turned it out when you went to bed, and the proprietor told me that in no case was any advantage taken by the visitors by burning it all night. I believe, myself, that in Australia above all places, being a new country, where gas is dear and money plentiful, and where land is rising so enormously in value, there is a great future for the electric light. If anything in this world should revive the drooping energies of a body of shareholders it is electricity. With your assistance I believe we shall be in a stronger position next year. I might have gone into a variety of details on a dozen different matters, but you are all men of business and as good judges as I am of what is best to be done. I invite you to ask any questions, to sit in council, as it were, with us, and to give us your advice. I would ask the shareholders to consider this point—whether it would not be advisable for two or three of them, either large or small, to consult with us on the affairs of the Company, and to advise with us, first, as to the desirability of raising some new capital; secondly, the mode in which it should be accomplished; and, thirdly, to what purpose that money, when raised, should be devoted. If they would do that a circular might be issued calling the attention of the shareholders to the matter. I feel that we are like men going on board a ship who have eaten their provisions. We have such a small sum of money in hand that we are hampered in every direction. We are afraid to go boldly into any great thing, and it was with considerable fear at first that the Board ventured on the contract at Melbourne (cheers). I will now conclude by moving—

"*That the report of the Directors and the accounts appended thereto be received and adopted.*"

Mr. GUESDON seconded the motion. He regarded the Directors not as the servants of the shareholders, as the Chairman had said, but as their managing partners. With respect to electricity they might reasonably look forward with confidence that it must be the light of the future. Gas had an immense struggle before it superseded oil, and for many years gas was considered the most perfect light we could have. Now, however, there was no doubt that electricity would supersede gas, and he said so notwithstanding the fact that he was interested in gas as a shareholder. He strongly urged the shareholders to place the Company in a fair position to fight the battle that was before it. They were now working at a disadvantage, and they could not achieve success without more money. He should certainly be ready to take his share in any issue of Preference shares which the Directors might decide upon. He was an Englishman, and he did not like to see them cut out by others, and especially by foreigners. It must be a matter of great regret to Englishmen to see so much business which ought to be in their own hands in the hands of foreigners. In the case of the Company the shareholders must exercise a little patience, and certainly more money must be provided, and he urged the shareholders to respond to any appeal that the Directors might make to them in order that the Company might have a fair chance of success.

Mr. MORRISON agreed with the Chairman that the electric light was in its infancy. He (the speaker) had just returned from the United States, where the development of the electric light was something extraordinary. He saw no reason why it should not progress in a similar way in this country. He agreed that electricity could be supplied as cheaply as gas, particularly with a large centre of supply. He thought the meeting was held unduly late after the making up of the accounts, and he urged that in future it should be held sooner. He congratulated the Directors on the appointment of Messrs. Gibbs, Bright and Co., of Melbourne, as consulting agents to the Company. He thought the shareholders owed to the Board a considerable debt of gratitude in having secured the contract for lighting the Melbourne Exhibition, not only for the profit that was made upon the work, but for the encouragement which had thus been given to an enterprise, in the prosperity of which they were so much interested. He believed that India offered the best field for the electric light.

Sir HENRY HOARE asked if the balance carried down was the amount brought down as debtor balance.

The CHAIRMAN: Yes, it is for the last seven years.

Mr. INCE said he had listened with the deepest interest to the remarks which the Chairman had made, and he was amazed that the Directors were able to carry out the arrangements referred to with respect to the Exhibition at Melbourne with practically no credit at their backs. They must all congratulate the Directors on the successful way in which they had managed the business. He had also listened with great gratification to the remarks which had fallen from the Chairman as to the starting of some central station. He was perfectly confident that the correct course for the Company to adopt would be to raise some further capital for the purpose of erecting a central station at some place which the Board might fix upon. He thought with Mr. Morrison that India would be the best basis to start operations upon with new capital. He believed they would be enabled to pay 7 per cent. upon the capital, and that there would be a handsome surplus on the working of the station; and he believed that, having started one station, it would only be a very short time before they brought the whole of their capital to par, or nearly the whole of it, as it might be wise to write off a part. The shareholders could not hope to achieve the success which they were all looking for unless additional capital were found, upon which, after all, the future of the Company seemed to depend. He would certainly be prepared to take his proportion of any extra capital that might be raised.

Mr. BENJAMIN KISCH desired to add his testimony to the gratification with which the shareholders must have listened to the observations of the Chairman.

Mr. VERITY said that all the shareholders would sympathise with the Directors. They had had a lot of trouble, and business had been bad, but what he wanted to point out was that they had been losing money each

THE NON-CONDUCTOR OF ELECTRICITY.

WAREHOUSE.

VULCANISED FIBRE,
PATENTED.

This new material is supplied in two qualities, Flexible and Hard.
The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.
It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.
The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.
Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.

year, and unless something were done before they next met he thought it would really be a question for the shareholders to talk about shutting up shop.

The CHAIRMAN: I do not see that at all.

Mr. VERITY observed that at their last meeting they had the control of the lamp patents throughout the whole field of their operations, but he believed that a recent judicial decision had altered their position in that respect materially. He could not understand what better position the Company would be in if they found extra capital for the purpose of starting a central station than they would be in if the matter were entrusted to local gentlemen. He considered it doubtful whether four or five gentlemen, members of the Board in this country, could control the working of a central station in the Colonies.

Col. WILKINSON gathered from what the Chairman had said that the Company had secured a most advantageous contract in Melbourne, but he desired to know whether the profit referred to by the Chairman was assured.

The CHAIRMAN: Absolutely assured under a sealed contract, and it will be realised, I should think, by the end of February. Our contract is with the Commissioners of the Exhibition at Melbourne, and under the arrangement it was agreed that within one month after the delivery of the plant and its acceptance by the Commissioners 90 per cent. of the amount which was placed for any particular engine or any portion of the plant should be remitted to England. That has been done regularly on the first Monday of every month, I think. Up to the present time about 90 per cent. of the money due to us has thus been paid. The balance of 10 per cent. will be paid to us within one month of the closing of the Exhibition, and, according to the Company's contract, the Exhibition was to be open for six months only. If it should be open for a longer period the Company will be entitled to cash for the full amount of the contract. I have referred to the statement made by the Commissioners in expressing their satisfaction at the lighting. Perhaps I had better read the extract. They say:—"Referring to the lighting of the building by means of the electric light, the Executive has great pleasure in stating that, after a month's trial of what is stated to be the largest single installation in the history of electric lighting ever attempted by a single company, it has proved a marked success" (cheers).

Mr. McMILLAN said he thought that what had happened during the past year had justified the advice he had given to the shareholders at the last meeting—to leave their affairs in the hands of the Directors. He was pleased to find that the confidence which the shareholders then reposed in the Directors had been fully borne out.

The CHAIRMAN, in further reply to questions, expressed regret that they had not be able to do any business in India. The stock which they had in hand there had been taken over from the Edison Company. The plant used for lighting the Melbourne Exhibition was absolutely sold to the authorities there. It would be taken over by the Government after the closing of the Exhibition and used by them on railways and other public works. They would certainly be able to place some of the Preference shares which might be issued through the Australian Electric Company. They had endeavoured to obtain payment of the calls in arrears, but they had failed to receive any more. The amount was only £1.500, which he did not think a very large sum considering that they had a capital of £120.000. They would probably forfeit the shares, as had been suggested, but they had not wanted to do that until the market price of the shares rose to something like 15s. or a pound, when they would be able to reissue them and get some money that way. The shares had lately been dealt in for the first time for years at a price equal to about 27s. per share, including the liability of 10s. on them. The longest lane had a turning, and he really thought that they could see the corner. They had intended to meet earlier, but delayed in order that they might be able to give some intelligence which would be regarded as of a gratifying nature by the shareholders respecting the working of the electric light at the Melbourne Exhibition. As Mr. Verity must be perfectly well aware, when once a central station was put up there was no difficulty in working the light, nor did he understand how Mr. Verity, in the face of what had been said at the meeting, could say that they were worse off now than they were a year ago. The fact was directly the opposite. He then put the resolution, and it was carried unanimously.

The retiring Directors, Messrs. Van Tromp and Sanderson, and the Auditors, Messrs. Deloitte, Dever and Co., were unanimously re-elected.

On the motion of Mr. INCE, seconded by Mr. VERITY, a vote of thanks was passed to the Chairman and Directors.

The CHAIRMAN briefly acknowledged the compliment.

It was decided to leave the question of the issue of Preference shares with the Directors.

The CHAIRMAN said that that being so the Directors would, at the proper time, issue a circular on the matter.

The proceedings then terminated.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 549.—Vol. XXII. FRIDAY, NOVEMBER 23, 1888. Price 4d.

NOTES.

As we announce elsewhere, the Committee of the Electrical Trades Section have decided to recommend the Board of Trade to increase the unit of electrical supply from 1,000 to 10,000 watt-hours. Concerning the reasons for this proposal, our readers may be referred to our leader in the present issue. We believe that good ground exists for this change, notwithstanding that it must give rise for a time to some confusion in the classification of dynamos. The unit of output of a dynamo being a rate of doing work is, of course, distinct from the unit in question, but in practice it has been found desirable that they should each rest upon the same numerical basis. It is to be hoped, therefore, that those dynamo-makers who at present speak of their machines in terms of the unit of 1,000 watts will consent to shift the decimal point. The effect of the value of the electrical unit being further removed from that of the horse-power will, we think, be advantageous in itself.

The meeting held yesterday to promote the laying of a Pacific cable from Canada to Australia, although described as an influential one, was conspicuously wanting in men of practical knowledge and experience connected with submarine cable laying. Probably this fact will account for the extraordinary statements confidently put forward from the platform to induce the audience to take a favourable view of the financial aspects of the scheme. Of course the merchants and shippers present were decidedly anxious to reduce the Australian cable tariff; but it by no means follows that these gentlemen will provide the money for reducing rates out of their own pockets, still less that the British Government will do so.

We commend to the notice of the Gas Journals, who are still much exercised in their minds over the Deptford Scheme, the letter of our New York correspondent in the present issue, in which he quotes the President of the American Gas Light Association, who, in a recent address, set himself to discover the reason for the great increase in the consumption of gas in the States. He arrived at the conclusion—not, indeed, a novel one—that the main reason was to be found in the extension of electric lighting, which had the effect of compelling people to use more light in every direction. Let the gas interest, therefore, again take heart of grace, and welcome the electric light as a true ally and indeed its very best friend.

In a leading article which appeared in our contemporary the *Electrical Review* last week on "The Future of Electric Railway Traction," we read that "Mr. Sprague himself was compelled to admit that accumulators are the only safe means as a motive power for street cars, and are therefore to be looked forward to in the future as the solution of the difficulty of electric traction for public thoroughfares. All this," proceeds our contemporary, "is very gratifying, but it does not in the least take us by surprise, as in this country there are not many electricians who would think otherwise, and we must take it that this question has already been settled in everybody's mind." As a general rule we do not care to criticise the views of contemporary English journals, and if we make an exception upon this occasion it must not be supposed that we are actuated by any hostile feeling. We do, however, feel bound to demur to the statement—coming from so influential a quarter—that English electricians have, as a body, arrived at the conclusion that the storage cell affords the only practicable solution of the electric traction problem. Our own impression is, indeed, very much to the contrary. Undoubtedly, an ideal solution would be furnished by an *ideal* cell. But how nearly does any cell in the market approximate to the ideal? We take it that such a cell will depreciate at one-nth the present rate, and will have n times the capacity with one-nth the weight per horse-power—the value of n being certainly not less than three or four.

Since writing the above we have turned to see what Mr. Sprague really did say on the subject (*The Electrician*, Nov. 9, 1888, p. 29), and we find that his views are practically identical with our own. "They will never," he says, "take 20,000 pounds weight up a 10 per cent. grade with a storage battery until it is in a good deal higher state of efficiency than it is to-day." Mr. Sprague then goes on to speak hopefully of an improved cell with which he is himself experimenting; and most sincerely do we trust that he, or somebody else, will meet with success in this direction. The relative merit of the overhead system is a question which has little more than academic interest in this country; but as to our contemporary's expressions of satisfaction in the attack of Mr. Leonard on the Richmond line, we have only to remark that the fact that even a moderate success should have been attained with such a rough-and-ready mode of erection poles stuck in the mud, and so on—speaks strongly in its favour; and at least it should be remembered that over fifty lines are now at work in America on this principle. The letter of our New York correspondent in this issue contains an account of a line at Topeka, fourteen miles

Digitized by Google

in length, with from thirty to forty cars, and involving an expenditure of over £40,000. This is to be worked by an overhead conductor. It is to be erected by the Thomson-Houston Company, and the Thomson-Houston Company are generally credited with a tolerably competent knowledge of what they are doing.

We believe, nevertheless, that storage cells have not yet been permitted to show what they really are capable of doing for electric traction. We refer to the fact that in every case that has come under our notice arrangements have been provided for coupling the cells in one or more sets in parallel so as to obtain a convenient E.M.F. for starting the motor and for variations of speed. In theory this is of course a highly tempting arrangement, particularly as it involves no immediate waste of energy; but in practice we regard it as most pernicious, and we are at a loss to account for the fact that those who are interested in the success of accumulators have so long tolerated it without protest. It is simply impossible that any set of cells should all have identically the same E.M.F., and wherever the slightest inequality exists the cells, if coupled in parallel, are placed in a condition of unstable equilibrium. When a cell once begins to take a discharging current it is never given any chance to recover, but is bound to go from bad to worse. We should therefore like to see all battery tramcars provided with a simple rheostat arrangement for starting on; and we believe that the extra cost would be defrayed many times over by the increased life of the cells.

Turning to another side of the traction question, a letter will be found in our correspondence columns in which Mr. Sprague replies to the recent criticism of Mr. Albion T. Snell. As Mr. Snell will no doubt have something to say on the subject next week, we content ourselves with the remark that Mr. Sprague scarcely does justice to the constructive part of Mr. Snell's criticism, in which he suggested a novel—and to our thinking a most valuable—method of determining the nature and extent of the internal losses in a motor. Mr. Sprague's plan of deducting ten per cent. from the electrical efficiency is doubtless good enough for many practical purposes, but then the original Paper (*The Electrician*, August 3rd, 1888, p. 409), upon which Mr. Snell's criticism was based, professed to be a full analysis of the performance of the Sprague motors, and for such a purpose a ten per cent. allowance for unknown losses is undeniably crude.

With reference to the letter which appeared last week under the heading of "Globular Lightning," and which we spoke of at the time as one of the most extraordinary statements of the kind which had come under our notice, we have since been given to understand that the books of the United Telephone Company contain no record of any indicators having been returned as damaged by lightning at the date quoted. Our informant also casts additional doubt upon the reliability of the source from which Mr. Wordingham obtained the story, stating that the line-foreman in question is well known to have been subject "to some very strange delusions." Having allowed the story to appear in our columns we feel bound to publish the above statement in the interests of scientific accuracy.

The third annual report of the Old Students' Association of the City and Guilds of London Technological Institute (to quote its full style and title), which now lies before us, offers such plentiful evidence of vitality that it is impossible to doubt that the future of the Association will be permanently and increasingly successful. There are now on the roll no less than 142 Members and Associates, of whom 49 were elected during the past year. The movement was originally started in connection only with the Finsbury Technical College, but in December last the title of the Association was altered as above with a view of extending the membership to the Central Institution in Exhibition-road, and the other branches. Under the Presidency of Mr. W. F. Pettigrew, 14 meetings in all have been held, including in that number a visit to the London and South Western Railway Works, two highly successful Smoking Concerts, and the Annual Dinner. Out of the nine Papers which were read at the ordinary meetings no less than six dealt with electrical subjects. Each of these Papers was submitted for examination to Professors Thompson, Meldola and Perry, who have awarded the Medal of the Association to Mr. Regd. J. Jones, for his Paper on "Installation Breakdowns." In communicating the decision of the examiners, Prof. Perry said "The Papers are all such as would be gladly accepted by the Councils of the various Societies before which Papers on such subjects are read." Perhaps we may be permitted without impropriety to express our entire agreement with Prof. Perry's remark. A higher tribute to the success both of the Association and the Institute with which it is connected it would be impossible to give.

It is pleasant to note that the Westinghouse men who are now in this country speak enthusiastically, not only of the outlook for the alternating current in general, and of the great organisation with which they are associated in particular, but also of the highly remarkable man who is at the head of its affairs. Mr. Geo. Westinghouse, jun., without being a highly-skilled electrician, has evidently a competent knowledge of the details of electrical engineering; and while he has in his employ a number of electricians—several of them Englishmen—of more than average merit, yet his own advice and experience has probably had more to do with the extraordinary success of the Company than is generally supposed. The wise and liberal policy adopted by the Westinghouse Company towards its technical officers has also undoubtedly contributed largely to that success. In this respect we are sorry to have to believe that with but few exceptions the leading English electrical firms and companies will not stand a favourable comparison. It is an open secret that the majority of the men who occupy similar positions in this country are by no means contented with the treatment which they receive. The grounds of this discontent are not always the same, and probably it is not always in the power of the company to remove them. But a better state of things would undoubtedly exist if the identity of interest which subsists between the company and its technical officers were more fully recognised. The Westinghouse Company seems

Digitized by Google

always anxious to acknowledge the share of each of its *employés* in the development of their system; and we believe we are correct in saying that it adopts the principle of attaching as far as possible the name of one of its technical officers to each of the principal features of its system. This spirit—although by no means altogether wanting here—has been conspicuously absent in some cases we could name; and there are men who have done good work whose names are scarcely known in the profession owing to the unwillingness of their employers to let it be seen how much they have been indebted to the scientific ability of their own officers. This is a short-sighted policy, and in the long run does not conduce to the reputation of the employers.

A RECENT correspondent of *The Times* advocates the teaching of physical science as a cure for national mendacity, which he (and others beside him) thinks is growing at an alarming pace. In this case the evil, if not the cure, is to be sought in the region of politics. The art of public mendacity has been cultivated just in proportion as the audience on which it can be profitably practised has been popularised. If physical science teaching would cure the democracy of its toleration of untruths the "Cry for Useless Knowledge" ought to be answered at once, notwithstanding Lord ARMSTRONG. But it would be simpler and cheaper to begin at the other end. Why not make admission to Parliament subject to a rigid examination in physical science? Here again, however, we should have to take coercive measures against people called "Crammers," if we really desired to put an end to the telling of things which go by that name.

"CAN such things be?" Apparently they can, for, unless the *Newcastle Leader* has been hoaxed, the Hexham Local Board is discussing with perfect seriousness an offer of Mr. MILBURN to light the town with primary batteries and 10 candle-power lamps (!) *at the rate of ½d. per dozen lamps per hour.* We devoted some little space to Mr. MILBURN last week, and have no room to do more than to assert with all due solemnity that the scheme is utterly impracticable; and upon this statement we are prepared to stake our professional reputation.

The Patents Bill.—On the order to go into Committee on the Patents, Designs, and Trade Marks Bill last Monday, Mr. Biggar objected, and, although appealed to by Mr. Mundella, persisted in his objection, and the order was postponed.

Paddington Vestry.—The Electric Lighting Committee of the Paddington Vestry has been authorised to obtain the advice of Prof. George Forbes upon the electric lighting scheme. Prof. Forbes has undertaken to furnish a report with plans by March 30th.

Renewal of Patents.—Mr. A. V. Newton has issued an address in pamphlet form recommending the reduction of fees for renewal of patents. The Patent Office is making a large profit, and Mr. Newton argues that the total cost of a patent should be reduced, or that the renewals should be in small sums spread over a longer period.

Illegal Fishing for Salmon and the Electric Light.—A Newcastle paper says:—We understand the Police Committee of the Tweed Commissioners are anxious to charter a steam tug to carry lights of 2,000 candle-power to search for nets set in the sea to catch salmon. Considerable difficulty, however, has been experienced in obtaining a vessel, the owners not caring to run the risks of the venture.

The Waterhouse System.—The Waterhouse Electric Company (of which Messrs. Shippey Brothers are the agents for England) have been awarded the Gold and two Silver Medals, at the recent Centennial Exhibition, Cincinnati; also two diplomas, the Gold Medal, and three cash prizes at the Californian State Exhibition. This system seems to be making headway throughout the States.

Society of Telegraph-Engineers and Electricians Students' Meeting.—A Students' Meeting was held on Thursday, November 15th, Prof. J. A. Fleming, M.A., D.Sc., in the chair. Mr. C. G. Lamb, B.Sc., read a paper entitled "A Résumé of the Question of Electrical Oscillations." Prof. Fleming also made some remarks on the same subject. A short discussion followed, in which Messrs. E. W. Smith, W. H. Shephard, and Rance took part.

Robey and Co.'s Engine at Glasgow.—We learn that the very fine 300 horse-power Robey engine used in the Electric Light Department at the Glasgow Exhibition is to remain in Glasgow, having been purchased by Messrs. J. and G. Thompson, the well-known engineers and shipbuilders, Clydebank, Glasgow, for their own use. Considering the number of engine builders there are in Glasgow, many of whom had engines in the Exhibition, this is undoubtedly a high compliment to Messrs. Robey and Co.

A Small Tragic Incident.—Mr. H. Palethorpe writes us from Dudley, as follows:—"For the last three years I have run a 4,000 candle-power arc lamp at the top of my sausage factory, Market Place, Dudley. Last Saturday evening, after burning for about two hours, the lamp stopped. The engineer went up to learn the cause, when he found a little bird, smaller than a sparrow, between the carbons, quite burnt up. The little fellow, attracted by the glare, had entered the lamp through a broken part of the globe."

The Telephone in Finland.—A correspondent writing from Nystad sends us the following interesting information respecting telephonic enterprise in Finland. A telephone line has just been completed between the towns of Abo, Nystad, Raumo, and Bjorneborg, a total distance of 168 versts (113 miles). The transmission is good, although the line runs nearly half the way parallel with Government telegraph wires connecting the cable station of the Great Northern Telegraph Company with St. Petersburg. Two of these wires are worked with the Hughes apparatus, which gives rise to rather strong inductive effects.

The Electro-Harmonic Society.—The concert of this society on November 30th (which is a "Ladies' Night") promises to be of a specially attractive character, a programme of peculiar excellence having been arranged for. The following amateurs have kindly consented to take part:—Mrs. A. Siemens, Miss Spagnoletti, Mr. George Clues, Mrs. Theobald, Miss Mary Doughty, Mr. T. H. Harrison, Miss Edith Doughty Mr. T. E. Gatehouse, Mr. W. Stepney Rawson, Mrs. J. Elvin, Miss Rawson, Miss Margaret Doughty, Mr. Alex. Siemens, and Mr. Alfred Izard. There will also be some recitations by the Rev. George Bell Doughty.

Electric Lighting Overhead Wires.—In the House of Commons, on Thursday, the 15th, in reply to Mr. Bradlaugh, Sir M. Hicks-Beach said that no overhead wires for the purpose of electric lighting had been sanctioned so far. He could not make any definite promise with regard to future applications on the subject with reference to the metropolis; but certainly he

Digitized by Google

should not be disposed to sanction such appplications. Mr. Brunner asked whether the right hon. gentleman had power to prohibit the erection of such wires in the metropolis, and Sir M. Hicks-Beach in reply said that was a question he would rather not answer at present.

The Radiometer.—Mr. W. Crookes has presented to the Department of Science and Art a collection of 68 radiometers and similar instruments, for permanent exhibition in the Science Galleries of the South Kensington Museum. They illustrate the steps by which he was led to the construction of the radiometer, and to the production of motion and of phosphorescence by streams of electrified molecules in high vacua. Many of the instruments are of the greatest historical interest. Among them is included the first radiometer, with many others, which are described in Mr. Crookes's Papers in the *Philosophical Transactions* of the Royal Society. Nearly all the instruments are in working order.

The Indian Telegraph Service.—A Calcutta paper says:—"The Sub-Assistant Superintendents of the Telegraph Department are about to memoralise the Director-General against the exclusive recruitment of Assistant Superintendents from England, a practice which shuts the Sub-Assistants out from all hope of rising to a higher rate of pay than Rs. 350 a month, and is besides contrary to the promises contained in the late Colonel D. G. Robinson's memorandum on reorganisation, which has since 1865 been regarded as the basis of the term of service. What the memorialists ask is that the present impassable gulf between the two grades should be bridged over by the promotion of experienced sub-assistants, who would thus, as a class, be given the prospect of reaching Rs.450 a month before retirement."

Electric Transmission of Power at Weissembach.—A cement manufacturer at Weissembach, near Triestang (Austria), finding it necessary to increase the power at one of his two mills, placed the matter in the hands of the firm of Siemens and Halske. The two mills were 300 metres apart, and at one of them a 3-metre waterfall was available: here a 20 horse-power Jouval turbine was installed. This turbine drives a 11½-unit compound Siemens and Halske dynamo, running at 1,000 revolutions and giving 90 amperes at 130 volts. The motor at the other mill is also a Siemens-Halske compound machine. Arc and incandescent lamps are run off the transmission circuit, so that the dynamo drives the motor by day and supplies the lamps by night; a few lamps can be run during the day time without disturbing the power circuit.

Progress in New Zealand.—The *Marlborough News* of August 17 says that the Borough Council of Timaru, after an interview with Mr. Ashcroft, jun., who submitted an offer to light the streets with electricity, resolved to instruct the Works Committee to prepare specifications on which the electric company and local gas company may tender for lighting the streets with about 100 lamps. It is also stated that the works of the Reefton Electric Light and Transmission of Power Company have been finished, and a satisfactory trial has been made. It is expected that by the end of the month the light will be in use in every street and dwelling in the town. The price charged is £3 per lamp per year, which is equal to 5s. per light per month. The entire plant cost £5,000, and was erected by W. Prince, of Dunedin. The shares of the company, on which 5s. is paid up, are now quoted at 3s. 3d., and are sought for.

Swansea.—At the last meeting of the Swansea Town Council, Mr. Martin moved the adoption of the minutes of the special committee *re* gas, which recommended that tenders be invited for the lighting of an area including the following streets:—Somerset-place, Mount-street, Wind-street, Castle-square, Castle-street, High-street (to Prince of Wales-road), Alexandra-road, Grove-place, De-la-Beche-street, Cradock-street, Union-street, Northampton-place, Dillwyn-street, Oxford-street, Goat-street, Temple-street, and Caer-street, and, to a certain extent, the streets leading therefrom. The present cost of lighting this area is £539. 13s. 8d. per annum, and the surveyor estimates that to light the same with electricity will cost an additional £175 per annum, or 30 per cent. more, while the illuminating power will be raised from 3,288 to 44,400 candles. It was decided, on the suggestion of Mr. Martin, to invite tenders for lighting the streets named by electricity.

The Wearing of Commutators.— Mr. Roger Tatham, of Rochdale, has recently devised an arrangement intending to prevent the uneven wearing of dynamo commutators. The brush-holder bars are free to slide to and fro, a cross-bar connecting them to secure simultaneous movement. A slow reciprocating motion is imparted to the brushes by means of a worm on the commutator which gears into a threaded shaft, which in turn gears into a cog-wheel provided with a connecting rod coupled to the brush-holder bars. The to-and-fro motion thus imparted to the brushes, it is claimed, ensures practically even and uniform wearing of the parts. By a somewhat similar contrivance an emery wheel or polisher is caused both to rotate and traverse to and fro, so that should the commutator be worn it can by this arrangement be easily turned true in its place. In cases where machines are required to work with the least possible alteration the device will probably be found useful.

Statistics of the Western Union Company.—The following table gives some interesting figures relating to the progress of the Western Union Company during the last twenty years. Between July, 1866, and the present time this company has paid the sum of 52,385,565 dollars (£10,477,113) in dividends. It should be remembered, however, that the apparent growth has been, in reality, largely due to absorptions of competing telegraph companies:—

Date.	Length.		Offices Open.	Telegrams Transmitted.	Revenue in Dollars.	Net Profit in Dollars.
	Line in Miles.	Wire in Miles.				
1868—1869	52,099	104,584	3,607	7,934,933	7,316,918	2,748,801
1878—1879	82,987	211,566	8,534	25,070,106	10,960,640	4,800,440
1883—1884	145,037	450,571	13,761	42,076,226	19,632,939	6,610,435
1884—1885	147,500	462,283	14,184	42,696,583	17,706,833	5,700,924
1885—1886	151,832	489,607	15,142	43,289,807	16,298,638	3,919,855
1886—1887	156,814	524,641	15,658	47,594,530	17,191,910	4,037,281
1887—1888	171,375	616,248	17,241	51,463,955	19,711,164	5,070,572

The Cost of Electric Lighting.—Messrs. Carey and Fricker (of 12, Delahay-street, S.W.) have issued a useful pamphlet on the above subject, which is designed to disabuse the public mind of the idea that the electric light is excessively costly, and that it possesses a dangerous and ricketty constitution. The writer—who states his case with commendable brevity and lucidity—does well to insist on the fact that the improvements which have of late years been effected in the design and construction of dynamos, lamps, and engines, have placed the business of electric lighting upon an assured footing, and, so far as isolated installations are concerned, have reduced it to the level of any other piece of engineering in which, in competent hands, there is nothing whatever of an uncertain or experimental nature. A diagram is given, showing the relative cost of gas and electric lighting for installations in mills and factories where a period of 1,500 hours of lighting per annum is attained. In this case, electricity ought undoubtedly to be cheaper than gas at 3s. where fairly large installations

Digitized by Google

are concerned; but we doubt whether the difference is quite as great as the writer supposes.

Sheffield.—On Saturday evening, by special permission, the members of the Sheffield Society of Engineers, about 40 in number, inspected the machinery and plant at the electric light station of the Sheffield Electric Lighting and Telephone Company (Limited). Mr. Fred. Tasker conducted the party, and explained in detail the construction and arrangement of engines and dynamos, storage batteries, &c. The main driving engines consist of a horizontal tandem compound, and high pressure coupled cylinders, of 40 horse-power, driving three "Thomson-Houston" dynamos, giving collectively a light equal to 300,000 candles; also a Phœnix dynamo, for charging the storage batteries. This station was described and illustrated in our issue of January 13th, 1888. At 8:15 the members adjourned to the Central Telephone Exchange. The arrangements for establishing communication between subscribers was courteously explained by the attendant in charge. The new American multiple board is now used, through which 30,000 messages per week are sent by over 500 subscribers. Seven miles of wire are used in connecting up this board, and there are about 5,400 separate soldered joints attached.

A New Arc Lamp.—We were asked the other day to witness a run with a new arc lamp patented by Messrs. Chapman and Dearing, of 345, Mile End-road. The negative carbon is fed up vertically by a rather crude arrangement (this, however, is to be replaced by a device somewhat of the Pilsen order), the arc being formed between it and the point of contact between two horizontal carbons in a straight line with one another and fed forward through tubes by springs. The lamp had been built to suit the machine driving it, and according to the ammeter in circuit, which we were told read about four amperes too high, was taking rather over 25 amperes. With this current the lamp burnt very fairly well, and so far as we could judge there appears to be some truth in the inventor's claim that it spreads the light considerably more than in the ordinary vertical carbon type. We were under the impression that Rapieff had covered all possible forms of this type; but the inventors maintain that he never used his positive carbons in the same straight line with one another forming a plain T with the negative, but always at an angle, and as it seems that they have obtained the German patent on appeal this is probably correct.

Royal Meteorological Society.—The first monthly meeting of this society for the present session was held on Wednesday evening, the 21st instant, at the Institution of Civil Engineers, 25, Great George-street, Westminster, Dr. W. Marcet, F.R.S., President, in the chair. The following Paper was read:—"Results of an Investigation of the Phenomena of English Thunderstorms during the years 1857–59," by Mr. G. J. Symons, F.R.S. This Paper was written nearly thirty years ago. It has now been communicated to the society at the request of the Thunderstorm Committee. The Paper contains a summary, chiefly in statistical form, of some of the results of an investigation into English thunderstorms and the accidents produced by lightning during the years 1857–59. The author found that in sheet lightning the most prevalent colour is white, then yellow, blue, and red; in forked lightning the order is nearly reversed, blue being more than twice as frequent as any other colour, then red, white, and most rarely yellow. Sheet lightning was seen about twice as often as forked.

The Hermite Process of Electro-Bleaching.—Mr. Hermite recently delivered a lecture at the University College, Nottingham, on the process of electrolytic bleaching with which his name is associated. He pointed out that advantages of the process were that every bleacher was enabled to produce his own bleaching agent, that there was greater economy than in the old processes, that the destruction of the fibre was inappreciable, and that the cost was constant. The first operation in the process was the electrolysis of a solution of magnesium chloride. By this the water and the salt were both decomposed, and the nascent oxygen of the water and the chlorine of the salt united, producing a very unstable compound, of intense bleaching power. The hydrogen gas and magnesium went to the negative electrode, and the latter formed magnesium oxide with the water, the hydrogen being disengaged. If in this liquor were introduced any coloured vegetable matter, the oxygen compound above mentioned at once bleached it, whilst the liberated chlorine combined with the free hydrogen to form hydro-chloric acid. This in its turn decomposed the magnesia, producing the initial chloride of magnesium. Therefore a complete cycle of changes went on in the process, and there was nothing exhausted except the water, which cost nothing. Mr. Hermite concluded by pointing out that in this process only half the motive power was necessary to bleach the same weight of coloured material as in the old processes, thus effecting a saving of 40 or 50 per cent. to the bleachers.

Kensington Vestry.—The following is a fuller summary (taken from a local journal) of the discussion at the Kensington Vestry, to which we referred briefly last week:—"The special committee appointed to consider matters on electric lighting reported that they had received a letter from the House-to-House Electric Light Supply Company (Limited), stating that several residents in Barkstone-gardens, Bramham-gardens, and Collingham-gardens were desirous of having a supply of electricity from the company's works adjoining the West Brompton Station, and that the owners of the new streets mentioned had consented to the laying of underground mains therein, provided that the same was done in compliance with the requirements of the vestry, and requesting permission to take up a portion of Richmond-road from the company's central station to Kempsford-gardens, through Kempsford-gardens and Earl's Court-square, across Earl's Court-road to Bramham-gardens, and along Earl's Court-road to Barkstone-gardens, for the purpose of connecting mains. The committee recommended, after great deliberation, that permission be given to the House-to-House Electric Supply Company (Limited) to lay down mains, &c., along the streets referred to in the application by way-leave, upon condition that, in the event of any general system being hereafter adopted by the vestry for the laying of mains, &c., the company undertake to change the mains now proposed to be laid in such manner as to conform to, and generally to be subject to, such future system. All the mains, &c., now proposed to be laid down, to be laid in such part of the roadway or footway, and generally on such conditions and in such mode, as may be approved by the vestry's surveyor. Several more or less incomprehensible amendments were put forward amid exciting speeches, but all were lost. Then, suddenly, toward midnight, Mr. W. A. Lindsay proposed that all electric lighting companies be given power to apply for a provisional order to carry on operations in the parish. This was seconded and carried by a large majority. A division was claimed, with the result that Mr. Lindsay's amendment was again carried by 38 votes to 19. Several members cried out that it was putting back two years' work, and many speeches were made as to the danger existing for the parish being placed at the mercy of the electric lighting companies. Mr. Duffield and Mr. Jordan said they would resign. The two years' labours of the committee had been undone. Mr. Campbell then proposed that the matter be adjourned for a fortnight. This was agreed to without a division."

LIGHTNING CONDUCTORS.—III.

BY DR. OLIVER LODGE.

(Continued from page 9.)

Further Alternative-Path Experiments, April, 1888.

20. A spark micrometer was now constructed out of a micrometer screw arrangement obtained from Lutz, of Paris, as part of a "Desains' apparatus" for measuring Newton's rings. It is depicted in various optical books—say, "Jamin et Bouty." Insulated knobs (of diameter, one 1·940, the other 1·965 centimetres) were supplied to this, and the distance between them could be varied and read with great ease and accuracy.

The pitch of the screw was one millimetre, and its micrometer head was divided into grades, so that actual readings were in 400ths of a millimetre. Seldom, however, was it necessary to read so close as this.

This instrument was always used henceforth to measure the length of the B spark. Knowing this length, the corresponding potential can be determined as follows :—

Connexion between Differences of Potential and Length of Spark.

21. The potential needed to give a spark in air between two flat plates d centimetres apart is 110 d electrostatic units, or 33,000 d volts. The corresponding spark length between two large spheres, of radii r and r' respectively, is b, where

$$\frac{1}{d} = \frac{1}{b} + \frac{2}{3r} - \frac{1}{3r'}.$$

(*See* Maxwell's "Electrical Papers of Cavendish," p. 386.)

In the present case the knobs are not large enough, in comparison with the usual length of spark, for this formula to accurately apply, but the error cannot be great if we take the potential corresponding to any very short spark, expressed in fractions of a centimetre, between the above micrometer knobs (which are each about 1 centimetre radius), as

$$\frac{99000\,b}{3+b} \text{ volts.}$$

For longer sparks or smaller knobs one must make a special series of experiments to compare one with another, and link all the different sized knobs together into one set, so that all their readings can be interpreted. To this end I have recently made a series of experiments, arranging all the pairs of knobs commonly used in parallel with a couple of large spheres, and adjusting them all so that a spark was willing to choose any of the intervals at random. The large spheres were more easily manageable than a couple of flat plates would have been; while calculation from them to flat plates is easy for all the lengths of spark tried. The results are shown in the annexed Table :—

Corresponding Lengths of Spark between Different Sized Spheres, Simultaneously Compared (Expressed in Centimetres).

Spark Micrometer Knobs, {1·97 / 1·94} cms. diameter. Commonly used for B spark.	Knobs of Voss Machine, {2·34 / 2·34} cms. diameter. Often used for A spark.	Universal Discharger, {1·38 / 1·41} cms. diameter. Often used.	Large Spheres, 12·1 cms. diameter. Used to compare with the others.	Corresponding Spark Length, calculated for flat plates from the preceding column. $\frac{18b}{18+b}$
·843	·87	·92	·86	·82
1·010	1·02	1·11	1·00	·95
1·410	1·38	1·62	1·33	1·24
1·455	1·41	1·74	1·41	1·31
1·783	1·73	2·28	1·60	1·47
2·130	1·93	3·30	1·74	1·59
2·365	2·17	3·70	1·85	1·68
2·638	2·37	4·14	1·97	1·78
2·972	2·57	5·60	2·10	1·88
4·361	3·85	7·92	2·50	2·19

Hence the length of A spark, 2·4 centimetres, between the knobs of the universal discharger, corresponds to a length of 1·50 centimetre between flat plates, and therefore to a potential difference of 50,000 volts.

Comparison of Wire, Gauze, and Foil.

22. In continuing the alternative-path experiments the first question I wished to examine was how far the distribution of the same amount of substance over different surface would affect the result ; I wished, in fact, to compare a round wire, a flat strip, and a bundle of detached wires, all as nearly alike as possible.

Three alternative paths were therefore prepared, each exactly 218 centimetres (about 7ft.) long. One was a piece of No. 12 copper wire, weighing 91·6 grammes. Another was a ribbon of copper foil 6·4 centimetres wide, and weighing 88·7 grammes. The third was a strip of fine regular copper wire gauze of the same width as the foil, consisting of 154 parallel wires, each about No. 34, with a corresponding woof. The weight of the whole gauze is 136·12, but only half this is effective, so its effective weight is 68·1 grammes. The total surface exposed by the foil is 12·8 times its length ; the surface exposed by the wire is ·77 times its length ; and the surface exposed by the effective wires of the gauze strip is 8·23 times its length.

The resistances, measured in an ordinary way, ought to be inversely as their weights, or roughly the same ; but, as so often happens, the copper wire turned out a bad material, and these were the results :—

Resistance of copper foil	·01125	ohm.
" " " gauze	·02931	"
" " " wire	·02446	"

23. The two gallon jars in series were used as before. The B knobs were those of the spark micrometer. The A knobs, however, instead of being those of the machine as heretofore, were the smaller knobs of a universal discharger, which was employed in order to obviate danger of any variation in the length of the A interval by reason of shaking.

The alternative path was sometimes connected to the outside of the jars direct, sometimes direct to the knobs of the spark micrometer. Hitherto no special care had been taken about this because the alternate paths used were so long ; but now that one began to use much shorter ones it was necessary to be careful where they were connected. Connecting them as directly as possible to the B knobs is plainly the best plan. As this had not been usually done hitherto, it was necessary to examine what sort of difference would be made by the change. The A knobs were adjusted to a distance of 2·4 centimetres apart, and the critical length of B sparks, when about half of them failed, is recorded below :—

Alternative Path.	Length of B Spark. Cms.
No. 12 copper wire, enclosing maximum area, and connecting outer coats of jars direct	·743
The same, but connecting B knobs direct, as in Fig. 5	·552
Ribbon of copper foil connecting B knobs, and enclosing area	·268
The same, but distorted from circular into long U form, so as to enclose much less area	·242
Ribbon of copper gauze, connecting knobs and enclosing area	·267
The same, but connecting outer coats of jars	·414
No alternative path at all. (Frequent spitting at A)	2·118
No. 19 copper wire round theatre, connecting knobs	1·649
The same, but connecting jars	1·698
No. 27 iron wire round theatre, connecting knobs	1·682
The same, but connecting jars	1·663
High liquid resistance, connecting knobs	2·080
No alternative path	2·080 or 2·00

But when no alternative path is used, the critical B length is less definite and sharp, and, instead of a single weak spark as with a high resistance, there is frequent fizzing and spitting at A ; though a strong spark passes at A whenever the B spark occurs.

24. Henceforth, the alternative path was connected direct to the knobs of the spark micrometer, so as to have no uncertainty about the effect of the short leads joining the outer coats of jars to these knobs.

In the next set of experiments, the same arrangement was continued precisely, except that sometimes two pint jars were

Digitized by Google

employed instead of the two gallon jars. The A spark was 2·4 centimetres as before.

	Alternative Path.	Length of B Spark.
Two pint jars; capacity in series, 733 centimetres.	None	1·906
	Liquid resistance	1·990
	No. 19 copper round room	1·380
	No. 18 iron „	1·358
	No. 27 „ „	1·305
	No. 1 copper „ with short stranded connections	1·297

In these experiments the iron is not maintaining its former position of superiority with respect to copper; *see* § 16. Thin iron is no longer able to beat the thickest copper, but appears about on an equality with it.

25. Since this seemed possibly due to a difference in the arrangement of the A part of the circuit—the part containing the jars, and which in the first of this series of papers we called the L loop, a part which hitherto had not been much attended to—the following modification was made:—One of the two gallon jars was connected up to the machine by means of one of the long leads round the theatre, so as to increase the self-induction of this part of the circuit enormously. The experiment was now repeated, with entirely fresh results. Everything else was the same as before.

	Alternative Path.	Length of B Spark.
Two gallon jars, but with one of them joined to machine through the No. 19 copper wire round the room.	No. 18 iron	·782 centim.

This experiment shows how vital is attention to every part of the circuit if the result is to be thoroughly understood. Hereafter, therefore, the circuit containing the jars and A knobs was much more carefully constructed, so that its dimensions could be exactly ascertained.

This last experiment is, moreover, the first to which we can apply our theory as set forth in the first of these articles. It does not happen to apply in its simplest form, however, when resistance can be neglected. The resistance of the long, thin leads seems to be an appreciable item in their impedance, and we shall have to take it into account.

(To be continued.)

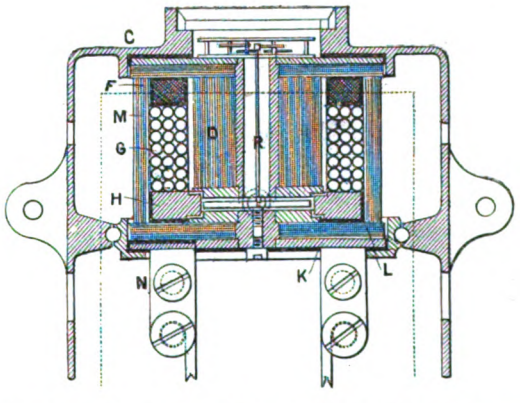
THE GROSVENOR GALLERY CENTRAL LIGHTING STATION.—II.

We this week supplement the account of the Grosvenor Gallery Central Station given in our issue of November 9th with a few additional details. We have already mentioned that the total number of lamps wired for this service is about 35,000. The number of customers at present supplied amounts to nearly 300, and the average power per installation is over 3,500 watts. This high figure arises from the fact that so many of the installations are fitted in theatres, restaurants, clubs, &c., and that the minimum charge made by the London Electric Supply Corporation is £20 per annum, so that small consumers are deterred from using the light. The current is to all intents and purposes always available, since the supply is only cut off once a week for about seven hours, and this early on Sunday morning.

The steam plant, it will be remembered, consists of four engines—two 35 horse-power (nominal) single-cylinder, Marshall, one coupled 500 horse-power, Marshall, and a 750 horse-power Corliss engine; one of the large dynamos being driven by the Marshall engines through countershafting, the other direct from the fly-wheel of the Corliss engine by rope gearing. The manner in which economical working is attained with these rather complicated arrangements is certainly very ingenious. The minimum output of the station is about 120,000 watts, which is quite sufficient to employ one of the Marshall engines economically. When, therefore, the demand upon the station is at its lowest, one Marshall is alone employed to drive the big Ferranti machine. As the demand increases, the second engine is started, the clutch coupling is thrown into gear, and the load is divided between the two engines; and later on the third Marshall engine is brought into play in the same way. When, however, the demand for current approaches the limit of the one dynamo, the Corliss engine is started on the second dynamo, which is brought up to the standard speed on open circuit, and the whole of the load is then transferred to this machine. This transfer is effected in a very simple manner. Each of the five main switches controlling the external circuits can be made to connect them with either machine. By means of these switches one circuit after another can be quickly transferred from the one dynamo to the other. As the output continues to increase the Marshalls are again started one by one, and the load is divided between the two dynamos. The same cycle of operations is gone through in the reverse way, as the demand upon the machines gradually declines to the minimum again. By these combinations a very fair degree of steam economy is attained, each engine being brought into use as soon as there is a sufficient load for it to manage. The switching on and off is so well effected that nothing beyond a momentary blink in the lights is noticed by the consumers.

The Ferranti Meter.

Since its first introduction, the Ferranti meter has been greatly improved in several important details. One of the latest forms is shown in the accompanying figure. The shunt



coil employed to give the field an initial value, independent of the current to be measured, is seen at F, G being the series coils and H a bronze disc, the whole being surrounded by laminated and insulated sheets of cast iron, M, which connect the laminated discs C and L. The rod R actuates the clockwork, and plunges in a mercury bath at H. The current enters at the terminal K, passes through the mercury to H, and thence through the series coils to the terminal N. Under the influence of the magnetic field and the current the mercury is caused to rotate, and as the resistance to rotation due to friction is proportional to the square of the speed, and the turning moment is proportional to the square of the current, the number of revolutions performed in a given time is a measure of the quantity of electricity which has traversed the meter in that time. Owing, however, to the resistance due to friction not following the above-mentioned law absolutely, and owing also to the friction of the clockwork, a sensible error is introduced. This error M. Ferranti ingeniously overcomes by employing the shunt coil already referred to, which secures an excess of electromagnetic action at the very moment when the frictional resistance of the clockwork is great, as compared with that of the mercury, *i.e.*, when the current is small. Further improvements are contemplated in this meter, and a very costly plant of American design is at the present moment being laid down at Mr. Ferranti's factory, for the purpose of turning out the improved type in large numbers. As many as fifty complete meters will be manufactured daily as soon as these arrangements are completed.

ELECTRIC WELDING.*

BY PROF. ELIHU THOMSON.

About a year and a-half ago I gave a description of the newly-developed art of electric welding, calling attention to the principles underlying its practice, and the results accomplished in the welding of various metals and alloys.

On the present occasion, the purpose is to show the apparatus, or at least a few forms of it, in operation, and to describe the working and construction.

Quite a number of types of apparatus have been developed, some of which are before us, and others we have at our factory at Lynn, Mass.

What we call the indirect, or induction, type takes current of comparatively high potential from a dynamo giving alternating currents, or from any other suitable source, such as a lighting supply line, and converts, or induces, from it a current of very low potential and great volume for electric welding, soldering, brazing and forming of metals. One form of apparatus, which will be used for welding iron and copper wires, is here before you (Fig. 1).

The "direct" type generates the currents needed directly from belt power or mechanical energy, and consists of a specially organised dynamo provided with a set of welding clamps. In fact, the needs of electric welding have given rise to a number of special and somewhat curious types of dynamos, which might not otherwise ever have been invented or constructed. But one of these forms is here shown, a number of others having been designed and constructed, and others again are undergoing construction. Fig. 2 is an example of a type of direct-welding dynamo, similar to the one on the platform, belted to the Institute engine.

The storage battery, properly arranged, constitutes another type. It is charged from a line, or by a small dynamo kept running constantly by power. Since the welding or heavy-discharge currents are only needed at intervals, a comparatively small dynamo will

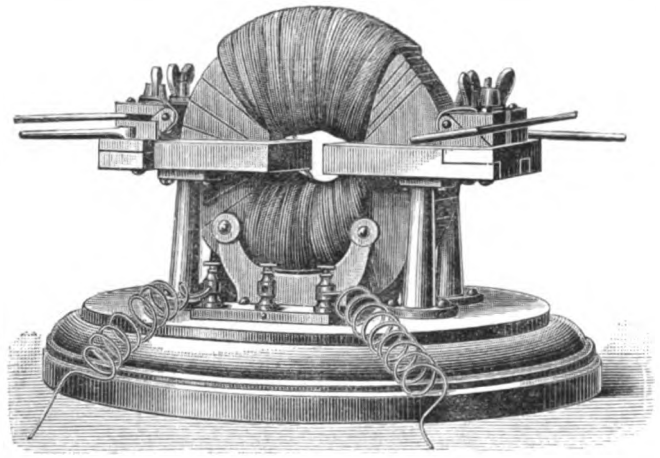

Fig. 1.

usually suffice for the charging. We have used a suitable cell of storage battery quite successfully in electric welding. Even primary batteries may, if of sufficiently low internal resistance, be used for the work, but are comparatively expensive to run.

Variations in the proportion and details, especially of the clamping devices, are made to suit the nature and size of the work to be done, and the shape of the pieces to be handled.

It may be mentioned that for some purposes a combined engine and dynamo for welding may come into use, especially where the work is intermittent. Thus an apparatus in all respects like a steam fire engine, but with a dynamo generating the requisite currents and substituted for the pumps, would be useful where portability is requisite and comparatively heavy work is to be done in isolated localities. The fact that the work is intermittent permits the use of less boiler capacity than would be the case were the plant to be under full load continuously.

I call attention to the numerous examples of work done as exhibited by the specimens which are found on the two sample boards before you, and upon the table. Here is a unique specimen, a shaft with two collars, formed without any welding at all, by simply pressing it endwise by the clamps with the current put on.

Here, again, is a very curious piece, which I am sure could not be produced at all without such apparatus as is shown here. It demonstrates the rapidity with which work can be done, and the localisation of the heating effects.

The specimen referred to is one in which a bar has been put through a hole in a flat piece of wood, and burrs raised on the bar at both sides of the wood, so that the wood is held between the two expansions in the bar, and almost pinched between them. The operation was so quickly done that the heat had not time to char the wood and enlarge the hole; or, if I may be permitted to say it, the wood had not time to find out that it should burn.

Among the specimens here shown are rings, cast-iron pieces, various tools constructed by use of electric welding, chains and links, &c. The various metallic alloys, as brass, German silver, are seen, in addition to heterogeneous welds or welds of different metals one to the other.

Many persons are puzzled to know how a ring can be welded at all by the current, especially such small and thick rings as are here shown, but there is no mystery about it. The current goes by the short path in greatest amount, and so welds the ring. This is particularly true of alternating currents of rather rapid rate, and, in fact, we have organised devices which absolutely prevent more than a small fraction of the current going around the ring. To do this we have only to establish conditions such that a current going around the ring has to produce magnetism in a closed iron core, while that which does the welding is comparatively free from such necessity. In such case, self-induction and resistance are both acting together to prevent flow around the ring instead of across the joint to be made.

Tests of tensile strength of electric welds are eminently satisfactory, and the occasion may some time come when I can present the results, or consider for you electric welding from the standpoint of its perfection as a welding process. Its utility is, however, already established. It does very many things which no other process can do or has done.

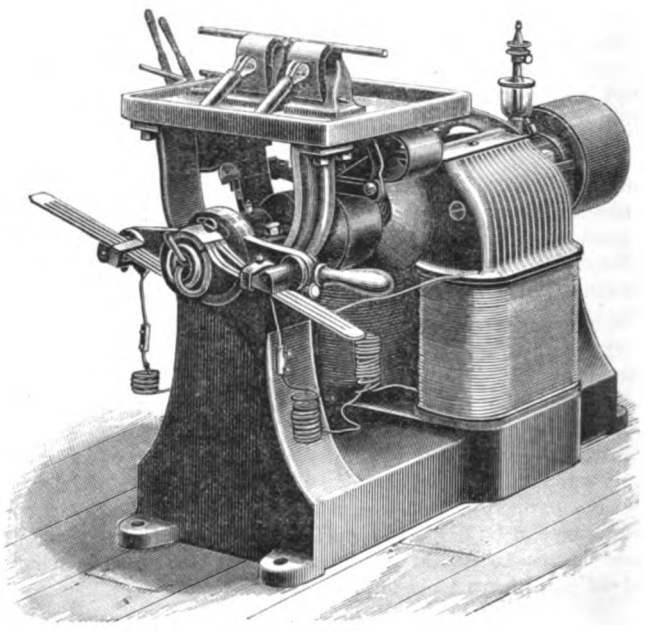

Fig. 2.

Here is a sample of lead pipe, welded without obstruction of its interior, and even without expansion outside. At a short distance away the pipe cannot be distinguished from a plain piece, and its exterior has been left just as it came out of the welding clamps.

Here, again, is a finished axe, with the steel cutting edge welded to the body by electrical means, the welding being the last operation done before final grinding for finish.

Here is a steel rake made by electricity, and several specimens illustrating the making of carpenters' squares by electric welding.

* Abstract of Paper read before the Franklin Institute, September 19th 1888.

ACCOUNT OF A HOUSE STRUCK BY LIGHTNING AT LISBON.

BY W. B. SAYERS.

A heavy thunderstorm broke over Lisbon and the surrounding country on Sunday, the 9th of September, lasting some twelve or thirteen hours. The following is an account of a flash that struck a house, which, by the courtesy of some friends, I had an opportunity of examining after the occurrence. The courses of the discharge through the house were so clearly indicated as to admit of no doubt whatever, so that I have been able to make the sketches (Fig. 1 and Fig. 2) without any undue exercise of the imagination.

The house is the summer resort of Illmo. Exmo. Snr. Carlos Eugino Almeida, and is called Chalet Torrezão. It is situated about eighteen miles west of Lisbon, at a beautiful little seaside

Digitized by Google

place called Estoril. The foundations rest on a rocky mound about 100ft. high, close to the sea shore, and in sight of the bar of the Tagus. There was no lightning rod.

Fig. 1 represents a front view of the house, which faces the sea southward. Fig. 2 is a cross-section, showing the paths taken by the discharge. The lightning struck the flag-post, the position of which is indicated at A (Figs. 1 and 2). The post was shivered into splinters, and was blown about over the space in front of the house like so much straw. From the flag-post the discharge passed, part through the window framing of a top floor bed room, indicated at B B in the sketches, and partly over the surface of the wall outside, and through the hole, shown at C, which it made in the said wall, apparently passing next between the floor boards and ceiling. The floor and ceiling in question remained undamaged for a distance of 5ft. from the point of entrance of the discharge, while the remaining distance traversed was burst open—the floor boards upwards, the ceiling boards downwards—precisely as though a gas explosion had taken place between them; but as there is no gas supply to the house this must have been the unaided work of the electric discharge. From D (Fig. 2) the current divided into two branches, while at E a second division took place. Apparently the largest branch was the one which passed through the first-floor front room. The walls and ceiling of this room were marked and smoked in a motley fashion nearly all over, all the marking radiating from the part of the ceiling which was burst down. An iron bedstead stood in the room, the bedding of which was set on fire, and the large hole, F, was situated just

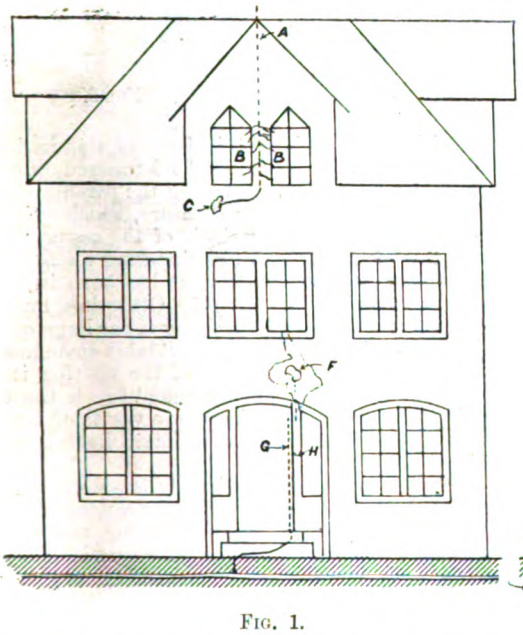

Fig. 1.

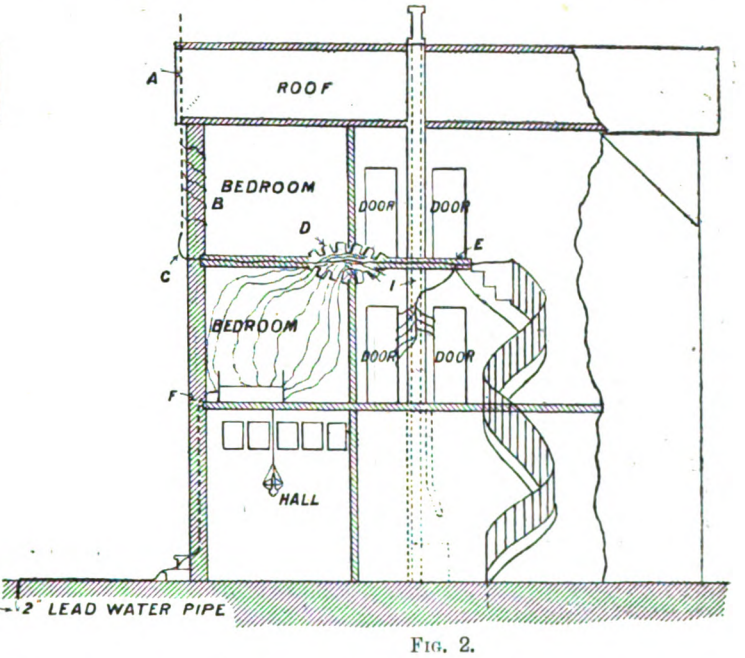

Fig. 2.

opposite one leg of the bedstead. I imagine that this branch must have divided itself out into numerous small branches, which ran more or less generally over the surfaces of the walls, and then leapt to the bedstead, where, gathering into one again, it leapt to the woodwork in the wall, descending by the door post and over two stone steps, and passing over the surface of the ground, a distance of 14ft., it disappeared, making a hole in the ground, at the bottom of which, 15in. from the surface, I found a 2in. lead pipe. The pipe was not in connection with any extended service, being only used to supply water from one part of the grounds to another. The ground in which it lay was damp, and I could find no mark where the discharge had gone to the pipe.

In the course of the passage from the bedstead to the ground were effects of extraordinary violence. The hole in the wall at F was about 2ft. 6in. wide at the widest part, and 3ft. 6in. long, the wall being composed of good stonework. The front door post at G was shattered into splinters, and the door also mangled, as though a steam roller had passed over it. In front of the doorpost stood a rectangular stone column, 6in. by 8½in. in section, shown at H, Fig. 1. This was broken through in the centre and thrown out of position, together with the heavy block on which it stood, and was taken down because unsafe. The corner of one of the stone steps was chipped off, a piece of stone measuring nearly half a cubic foot. From the stone steps to the hole where this branch went to earth there was a black track about 4in. wide, in which everything burnable was scorched up.

The path of the second branch of the discharge is indicated by a hole in the under side of the staircase about 3in. by 5in. (*see* E, Fig. 2), and by a scorched and smoky mark leading to the wall I (Fig. 2), where it divided, five small arms going over the surface of the wall into the room on the left-hand side, and three into the room on the right. About a yard or more inside the doors of the respective rooms the markings ended in conical holes in the plaster from 1in. to 3in. in diameter at the surface, and about equal depths. In nearly all the holes a corner of some piece of wood used in construction of the wall was visible at the apex of the hole, and I concluded at first that this portion of the discharge had found its way to earth through the general mass of the wall. I afterwards discovered, however, that the kitchen chimney, which in Portugal it is customary to make very thin and broad, so as not to thicken the walls, passed through the wall at this point. Some fallen soot on the top of the stove was all there was to be seen of the effects of the discharge in the kitchen below.

The third branch of the discharge which split off from the second at the point marked E (Fig. 2) made for the iron balustrade of the staircase, which is continuous from top to bottom. It passed along 6ft. of plaster partition, ripping the plaster out and baring the laths, and made an "arc" mark where it went on to the iron. A small wooden foot, on which the rail rested at the bottom, was split asunder, and one-half thrown out into the passage.

One thing struck me very forcibly with regard to the damage done to stonework, and that was that, with the exception of the corner which was split off the stone step, it was evidently caused by the violent disruption of woodwork in its vicinity, which must have amounted to a violent explosion. Window frames, door posts, doors, &c., were all torn and shattered in the vicinity of the path of the discharge, while the woodwork which had occupied the main path had disappeared, being literally shattered into straws. Two rows of windows, communicating with the rooms on each side of the hall, had scarcely a sign of glass left in them, and the paraffin lamp, which hung from the centre, was thrown down and broken to pieces.

THE PIEPER ARC LAMP.*

The form of arc lamp originally devised by M. Pieper is shown diagrammatically in Fig. 1. The rod A of the positive carbon holder is very light, and slides in a socket, which allows the lamp to be worked in almost any position. The electro-magnet B, shown vertical for simplicity, is really horizontal. The coils of this magnet are a shunt upon the arc. This magnet acts upon a vibrating armature, C, which is kept in position by the springs R R, and which has a transverse arm, D E, provided at either end with metallic shoes. The projecting piece F makes contact with the stop G at each oscillation, cutting the electro-magnet B out of circuit, and allowing the springs R R to bring back the armature C to its original position. The action of the lamp is as follows:—As soon as the coils of the electro-magnet B are traversed by a strong current, owing to the abnormal resistance of the arc, the armature C is attracted, the shoe D releases the rod A, while the shoe E presses against it and forces it down slightly. The electro-magnet is then cut out of circuit, and the armature takes up its original position. The current then again increases in the coils of B, and the cycle of operations is repeated. This mechanism is

* Translated from M. Hippolyte Fontaine's "Éclairage à l'Électricité," by kind permission of the author.

Digitized by Google

therefore nothing more than a small electric motor whose incessant vibrations give a continuous and exceedingly slow motion to the upper carbon holder. A series of screws allow all parts essential to the proper working of the lamp to be regulated as required. The arc is struck, as in the Bréguet lamp, by means of an electro-magnet excited by the main current, and placed under the negative carbon holder. This apparatus works well, but this is due chiefly to the ingenious and careful manner in which its construction is carried out, which shows in every little detail the handiwork of the skilled mechanic.

In his new lamp (Fig. 2) M. Pieper has greatly modified his mechanism. The electro-magnet A A', which is in parallel with the rest of the circuit, has two pair of poles; the external pair tend to revolve, attracted by the armatures N S (Fig. 3), the inside pair clutch the rod of the upper carbon holder. The socket B is fixed to this magnet, and terminates in a threaded portion, which engages in the female screw C. At the top of B there is a cross-piece, which is kept in position by springs. Inside C' there is a

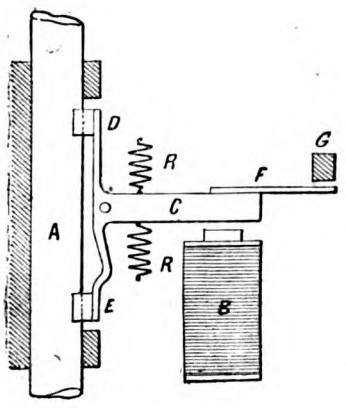

Fig. 1.

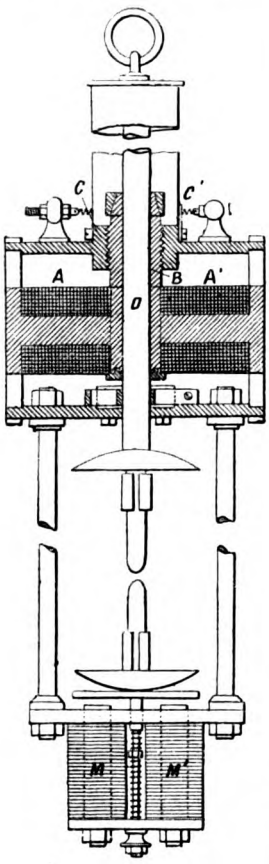

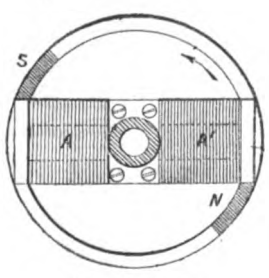

Figs. 2 and 3.

contact screw, which periodically cuts the electro-magnet out of circuit when it revolves. The movement of the rod D is controlled so as to prevent it from turning from right to left, or descending by the force of gravity. The arc is struck by the action of the electro-magnet M M'. As the arc lengthens, and the current in the coils A A' increases, the armature attracts the poles, and the magnet turns round from left to right, both B and D participate in this motion, and the carbon feeds down. The electro-magnet is now cut out of circuit by the contact screw, and the springs bring everything, except the rod D, back to its original position. The rod D cannot turn from right to left, and, moreover, it is no longer attracted by the magnet A A'. This action maintains the arc at its proper length as the carbons are consumed. The apparatus is carefully thought out, it is cheap, and works well, provided it is kept in good order. The smallest oxidisation of the rod D interferes with the working of the lamp.

PHYSICAL SOCIETY.

At a meeting of this society, held on Nov. 10, Prof. Reinold, F.R.S., president, in the chair, a Paper was read by Prof. J. A. Fleming,

On a Form of Standard Resistance Coil.

Prof. Fleming stated that he had for some time been endeavouring to devise a form of standard resistance coil which should be free from some of the defects of the ordinary form, shown in Fig. 1, which represents the form of standard coil adapted by the Committee of the British Association in 1865. It consists, as is well known, of a coil of silk-covered paraffined wire, contained in the space between an inner brass cylinder and an outer casing of brass of the form shown in Fig. 1, the ends of the coil being soldered to thick copper conductors as shown, and the space containing the coil being filled up with paraffin.

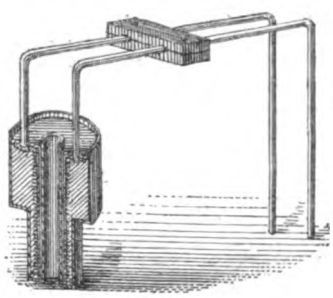

Fig. 1.

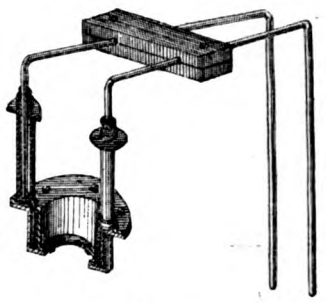

Fig. 2.

The principal objection to which this form of standard coil is open is that the whole of the coil cannot be immersed in melting ice, for if this were done, the upper surface of the paraffin would be cooled to such an extent as to condense moisture, which would produce a short circuit between the terminals of the copper conductors; and though there is not much short-circuiting when the standard is new, it becomes considerable when it has been in use for some time, and the lacquer gets worn off. Other less important defects of this form of standard are that, owing to the large quantity of paraffin, which is a bad conductor of heat, it takes some hours for the coil to assume the exact temperature of the melting ice, and that, owing to the length of the cylinder round which the coil is wound, the melting ice must be contained in a vessel of considerable depth, which makes it difficult to maintain its temperature uniform throughout.

The first attempt to overcome these defects is shown in Fig. 2, and consisted in using a shorter cylinder of larger internal diameter, with a smaller space between it and the outer casing, and enclosing the lower portions of the copper conductors in vertical brass tubes, insulated from them by air, the conductors being supported at each end of the tubes by means of ebonite washers. With this form

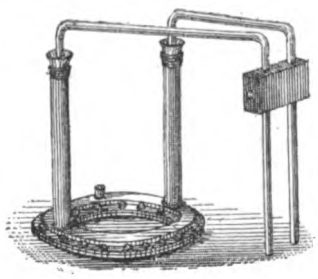

Fig. 3.

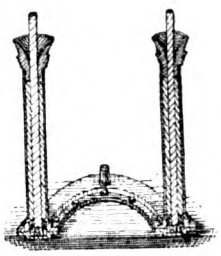

Fig. 4.

the trouble arising from deposition of moisture was diminished, but not entirely obviated. The next step was to still further increase the diameter, and diminish the length of the containing cylinders, and to cover the copper conductors with India-rubber tubes. This form was found satisfactory in every way, except that after a time the India-rubber was found to perish, and no longer protected the conductors.

The form finally adopted is shown in Figs. 3 and 4. In this instrument the coil is wound in a flat spiral, so as to reduce the length of the cylinders to a minimum. The copper conductors are insulated by a layer of air from the vertical tubes surrounding their lower portions, except at the ends of the tube, where a fluid insulator is used. The upper ends of the containing tubes terminate in ebonite cups, which are filled with paraffin oil when the instrument is used, which effectually prevents any creeping of moisture from the tube on to the conductor. The two annular

Digitized by Google

discs of brass are provided with flat groves in their opposed portions, and when the annular plates are screwed together the grooves form a closed ring of rectangular section, in which the coil, one or several layers in depth, according to its resistance, is contained. The coil is embedded in paraffin, but a free space is left in the groove of the upper plate. An opening, closed by a screw plug, is made through the upper plate into this groove, and before being used the plug is removed, and air is forced into the core while the instrument is immersed in water, when any defects in the joints will be shown by the air bubbling up through the water. With this flat coil a very shallow vessel can be used to contain the melting ice, and the coil case can itself be made to act as a stirrer by simply moving it up and down in the vessel. Prof. Fleming stated that this form of standard coil, which was exhibited to the meeting, had proved thoroughly satisfactory.

At the same meeting a Paper was read by Prof. J. V. JONES,

On the Coefficient of Mutual Induction of a Helix and a Coaxial Circle.

The author stated that he had recently been making a re-determination by Lorenz's method of the absolute unit of resistance. He had therefore had occasion to consider the best form of standard coil to be employed, and as the use of a single layer of wire presents considerable advantages he decided to replace the form of coil usually employed, consisting of several layers of wire wound upon a very short cylinder, by a single layer wound upon a longer cylinder. The treatment of the coil as a current sheet when the calculation is carried only to a first approximation, as, for example, in Lord Rayleigh's calculations, did not appear to be sufficiently accurate when applied to the coil and helix actually employed to enable a final result of the accuracy arrived at, namely, 1 in 10,000, to be obtained; and the author thought it would prove simpler, and also give a more reliable result, to calculate the coefficient of mutual induction between the coil and helix directly instead of carrying the current sheet method to a second approximation.

The helix employed consisted of silk-covered and paraffined wire one-fiftieth of an inch in diameter, wound upon a cylinder 22in. in diameter and 4in. in length, the wire being wound in a screw thread having a pitch of one-fortieth of an inch cut in the cylinder.

A method of calculation is given considering the wire as a helix whose equations are $y' = A\cos\theta'$, $z' = A\sin\theta'$, and $x' = k\theta$, those of the circle being $y = a\cos\theta$, and $z = a\sin\theta$. The general expression for M, viz., $\iint \frac{\cos\varepsilon}{r}\,ds\,ds'$, when applied to this case becomes

$$M = \int_0^{2\pi}\int_0^{\Theta} \frac{-\Theta A a \cos(\theta' - \theta)\,d\theta\,d\theta'}{\sqrt{A^2 + a^2 - 2Aa\cos(\theta - \theta') + k^2\theta'^2}},$$

where Θ is the total angle of the helix. An integration is performed by change of variables, making $\theta - \theta' = \phi'$ and $\theta' = \phi$. When Θ is an integral multiple of π (say n), the integral is expressible in terms of a series, involving the complete elliptic integrals E and F of modulus $c = \frac{\sqrt{4Aa}}{A+a}$, the expression for M being

$$M = 4n\pi\,\frac{Aa}{A+a}\,\Sigma(-1)^m \frac{1.3\ldots 2m-1}{2.4\ldots 2m}\,\frac{1}{2m+1}\left(\frac{x}{A+a}\right)^{2m} P_m,$$

where $x = kn\pi$,

and $$P_m = \int_0^{\frac{\pi}{2}} \frac{\cos 2\phi\,d\phi}{(1 - c^2\sin^2\phi)^{\frac{2m+1}{2}}}.$$

If $$Q_m = \int_0^{\frac{\pi}{2}} \frac{d\phi}{(1 - c^2\sin^2\phi)^{\frac{2m+1}{2}}},$$

then $$P_m = \left(1 - \frac{2}{c^2}\right)Q_m + \frac{2}{c^2}Q_{m-1} \quad \ldots \quad (B)$$

and $$Q_m = Q_{m-1} + \frac{c}{2m-1}\,\frac{d}{dc}\,Q_{m-1} \quad \ldots \quad (C)$$

Observing that $Q_0 = F(c)$ and $Q_{-1} = E(c)$, P_1, P_2, P_3 may be expressed in terms of $F(c)$, $E(c)$, and c.

Instead of calculating each term P_m independently, it is found easier in practice to deduce the successive values from equations (B) and (C), combined with $(1 - c^2)\,Q_1 = E$ and its derivatives.

The series obtained in this manner were found to be very convenient for the purposes of calculation. The author has compared the result obtained by his method with that obtained by Lord Rayleigh's approximation formula in the case of a helix of radius 10 inches, and an axial length of 4 inches, and a coaxial circle of radius 5 inches in its mean plane, and he finds by his own method,

$$M = n \times 53{\cdot}259,$$

and by Lord Rayleigh's method,

$$M = n \times 53{\cdot}317,$$

a difference of nearly one part in a thousand, which is therefore of importance.

Prof. PERRY observed that practical formulæ of the nature obtained by the author were of great value to electrical engineers. He inquired whether the author had made any attempt to obtain formulæ in which the thickness of the wire was taken into account, the current being assumed to be uniformly distributed through it. He also observed that, as far as he was aware, no one had yet obtained a practical formula for the strength of the field of a cylindrical coil, except for points at a considerable distance, or one which would give the coefficient of mutual induction between two coaxial cylindrical coils.

Prof. FLEMING stated that he had for some time been endeavouring to construct a standard of mutual induction, and the method which he adopted was to wind a coil of insulated wire upon a wooden tore or anchor ring of circular section, the wire being wound uniformly upon it, forming a coil similar to a Gramme ring. Then, if a secondary coil was wound over a portion of this ring, the coefficient of mutual induction was to a first approximation independent of the winding of the secondary coil. This arrangement formed a sort of condenser, and he had used it to check condenser measurements, the method adopted being to insert a ballistic galvanometer in the circuit of the secondary coil, and then to connect the ends of the primary coil to the terminals of a battery and suddenly reverse, observing the swing of the galvanometer.

The AUTHOR, in reply to Prof. Perry's question, stated that he had not investigated the effect of the thickness of the wire, as in the case of the coil and helix which he was using he was confident that this correction would not be as much as 1 part in 10,000. For the same reason he had not hesitated to use silk-covered wire in spite of the slight unevenness in the silk which, was unavoidable. The ideal standard would be a coil of wire covered only with a uniform layer of paraffin wound in a screw-thread. The paraffin would not undergo any sensible deformation for a very long time.

He stated that he had not carried out the calculation of the coefficient of mutual induction of a circular coil and a coaxial cylindrical helix to a second approximation, on the assumption that the helix was equivalent to a current sheet. If this were done the result would, no doubt, agree more closely with that obtained by his method, but the calculations would be much more complicated than those involved in the direct calculation. With regard to Prof. Fleming's anchor ring, he did not think it would be as good a form for a standard as a cylindrical coil wound upon a screw thread, as it would be very difficult to wind the wire uniformly upon the ring.

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny.
Editorial, Publishing and Printing Offices:

No. 1, SALISBURY COURT, FLEET STREET, LONDON, E.C.

Telephone No. 2714.

All Communications to be addressed to "The Electrician," 1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to "The Electrician."

All letters intended for insertion in "The Electrician," or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.

"The Electrician" is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.

"The Electrician" is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.

SPECIAL NOTICE.

Owing to the increase in the number of pages of "The Electrician," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.	6 months.	12 months.
For Foreign Parts and Colonies:—	s. d.	s. d.	s. d.
Within Postal Union	6 6	12 6	24 0
„ Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	14 6	28 0
The rates for the United Kingdom remain as follows:—	5 0	10 0	19 6

TO ADVERTISERS.

"The Electrician" offers exceptional advantages to Advertisers. **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

Trade Advertisements *intended for the current issue must be handed in not later than First Post on Thursday morning.*

Small Prepaid Advertisements *(for Rates see page xi.) are accepted up to 4:30 p.m. on Thursday.*

TECHNICAL PRINTING.

"The Electrician" Printing and Publishing Company (Limited) *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

The Electricians' Directory.

Royal 8vo. Cloth Boards, 3s. 6d., post free 4s.

At the commencement of each year is issued The Electricians' Directory and Handbook. *The Directory was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

THE DIRECTORY FOR 1889 IS IN PREPARATION,

And new names and addresses are now being received.

"THE ELECTRICAL WORLD" IN THE UNITED KINGDOM.

Arrangements have been made by which "The Electrical World" of New York can be obtained from "The Electrician" Office, 1, Salisbury-court, Fleet-street, London, E.C.

The Rate of Subscription (payable in advance), including postage, is **£1. 1s. 0d.** *per annum to this Country and Abroad.*

Single Copies of "The Electrical World" can also be obtained, **price 6d. each.**

The Rates for Advertisements in "The Electrical World" of New York can be obtained on application to "The Electrician" Printing and Publishing Company, Limited, as above.

"THE ELECTRICIAN" IN THE UNITED STATES.

Similarly, "The Electrician" can be obtained in America at the Offices of "The Electrical World," 168 to 177, Potter-building, New York.

"The Electrician" can also be obtained from D. Van Nostrand *23, Murray-street, and 27, Warren-street, New York.*

The Rate of Subscription for American Subscribers (payable in advance) is $6 per annum.

VOLUME XXI. OF "THE ELECTRICIAN."

Volume XXI. of "The Electrician" is NOW READY,
Price 12/6, post free 13/6.

Cases for Binding Volume XXI. are Now Ready, Price Two Shillings Post Free, Two Shillings and Threepence.

CENTRAL STATION LIGHTING AND THE BOARD OF TRADE.

The publication of the Kensington Court (Draft) License (*The Electrician*, Nov. 9th, p. 13) has served to direct attention afresh to the powers possessed by the Board of Trade under the Electric Lighting Act of 1882 and the Amendment Act of the present year. A careful study of these powers further results in affording additional evidence of the need for an organisation such as that which the electrical trades have just established under the auspices of the London Chamber of Commerce. It is, indeed, hardly too much to say that the Board of Trade is practically at liberty to frame whatsoever conditions it may see fit, within the general scope of the Acts, for the guidance, control and supervision of electric lighting

undertakers, whether under provisional orders or licenses. In these circumstances one of the first duties of the undertakers is on their part to endeavour to induce the BOARD OF TRADE to promulgate only such Regulations as will be generally acceptable to the electrical trades; and to this end it is obvious that an interchange of views, now rendered practicable by meetings at the CHAMBER, and a common understanding, will be of the utmost practical value.

Fortunately the case is not one of dogmatism and obstruction on the one hand, or laxity and exaction on the other. The undertakers desire only such reasonable latitude as experience and foresight would seem to warrant; and it is fair to admit that the BOARD OF TRADE has shown no disposition to hamper them by impossible conditions. The Kensington Regulations, some at least of which might be cited to the contrary, are, it is understood, of a tentative character, and are put forward to ascertain what kind of reception they will meet with. We have already pointed out some inconsistency in their wording leading to contradictory inferences which could hardly have been the work of a legal draftsman. It cannot be doubted that a representation from the trades concerned will, for example, result in making perfectly clear in any future issue to what extent, if at all, the undertakers are responsible for work which they have had no hand in performing. Met with moderation the Board will, we feel sure, give a respectful consideration to these and other points of difficulty which may be discovered and laid before it in respect to the administration of the Act.

We also feel satisfied that the manner in which the Electrical Trades Section has already entered upon a discussion of this and other cognate matters will conduce to good progress being made under the Act as now amended. To begin with, we learn that the Section is virtually agreed as regards certain points on which the interests of its members are not identical, and which, consequently, will not form the subject of joint representation to the BOARD OF TRADE or the Local Authorities. If this be the case, one of the chief preliminary obstacles to the smooth working of any trade organisation has been speedily overcome.

Having disposed of this internal difficulty, the Section has given its earliest attention to a subject of immediate practical importance. The BOARD OF TRADE is to be asked to alter the definition of the unit from 1,000 watt-hours to 10,000 watt-hours; the object of the change being to enable the price of a unit to be quoted within narrower limits. Under any definition an alteration of one farthing is practically the smallest change of price which can be effected; and under the BOARD OF TRADE'S standard this would usually amount to somewhere between two and three per cent. of the total charge. Upon a large scale of working it is evident that a more minute scale of adjustment will be desirable, and this can easily be effected by the proposed change in the definition of the unit.

Of even greater importance, but not so easy of solution, is the question arising out of the wiring the consumers' premises in the district in which the supply of electricity is compulsory. We have already alluded to the responsibility involved under these conditions. For the safety of the system as a whole, the undertaker ought certainly to have some guarantee that the wiring and fittings indoors have been properly done, since the consequence of a defect in these details may not always be confined to the premises on which it occurs. Where the undertakers *only* supply current the difficulty may perhaps be met by conferring upon them the right to inspect the fittings before current is turned on; but in cases where the Supply company contract for internal installation as well, it would be impossible to confer the right to reject the work of an outside firm without giving rise to much heartburning. On the other hand, it would not be fair, even if it were practicable, to prevent customers employing what firms they please to contract for the wiring and fitting. The LONDON ELECTRIC SUPPLY COMPANY have, we believe, experienced inconvenience and incurred some odium in this connection. A remedy agreeable to all parties is not yet ready to hand, there being only a general agreement at present that a multiplication of such functionaries as Mr. HEAPHY would, to say the least of it, be a *pis-aller*.

Concurrent action, however, on the part of the Electric Supply companies is advisable not only in relation with the BOARD OF TRADE, but also, and perhaps even more imperatively, with the Local Authorities. The need for this is forcibly exemplified by recent proceedings at the Kensington Vestry. Here the representatives of several companies were, it is said, successively interviewed, with the avowed object of seeing which would yield the most, particularly in respect of the compulsory purchase clause. Now, competition, in the usual commercial sense of the word, should be as unrestricted for electric lighting as for all other kinds of contracts, and we should be the last to countenance any suggestion to the contrary; but we do take exception to that form of competition which seeks to gain its end by contracting itself outside an Act of Parliament which is supposed to be binding upon all the competitors. In matters of tariff let there be an open market, but in respect of the compulsory purchase clause we think it most desirable that undertakers should stand loyally by the Act. In saying this we do not, of course, suggest that undertakers shall bind themselves beforehand not to sell until the expiry of forty-two years—that would be an absurd suggestion; all we mean is that no pledge on the subject ought to be given to the local authorities for the purpose of inducing them to adopt one system rather than another. To do so would be to stultify the work of those to whom the Amendment Act of 1888 has been due, besides being a gratuitously suicidal act on the part of the contractor.

RESEARCHES IN ATMOSPHERIC ELECTRICITY.*

BY PROF. LEONHARD WEBER, OF BRESLAU.

The experiments described in this Paper are a continuation of those undertaken at the request of the German Electrotechnic Union, and a preliminary report of them has already been published.† The present experiments were communicated to the (German) Committee for considering Danger from Lightning.

The first part of the Paper gives details of the erection of two experimental lightning rods on the summit of the Schneekoppe, one of the chain of Riesengebirge, and situate about 80 miles S.W. of Breslau. The common base of the two rods was a square of three metres side, and at each of its corners a wooden trestle was erected whose construction will be understood from the figure. The two vertical pieces are sunk to a depth of about ¾ metre into the hard rocky earth, and carry two horizontal cross-pieces. Between these latter rests the end of a wooden beam Q, insulated from them by the two glass cylinders A A′, each about 10 centimetres long and 7 centimetres diameter. The cylinders are kept dry by sulphuric acid surrounding them, and contained in the covered pans x x. The beam is clamped in position by an iron screw pressing on a piece of wood which rests on the upper glass cylinder. The two wooden beams Q support a single beam about 6 metres long, running at right angles to themselves and fastened to them by bolts. At the points of junction of these beams the two lightning rods were erected. Each is held in position by four iron supports, and also by three galvanised iron wires attached to the ends of the beams, which can be tightened up in the same way as the supporting wires of an ordinary telegraph post. The conductors are thus parallel, three metres apart and about 15½ metres high. They are tubular, and taper like a fishing rod, the diameter at the base being 7 centimetres and at the summit 1½ centimetre. On the top of each is a gilt sphere of 8 centimetres diameter. Just below this sphere is fixed an iron ring, by means of which any apparatus,

* Abstracted from *Electrotechnischer Zeitschrift*, April, 1888, by Dr. J. L. Howard.

† *Electrotechnischer Zeitschrift*, Bd. VIII., Heft 11, Nov., 1886.

Digitized by Google

such as slow matches or needle points, can be hoisted to the top for purposes of experiment.

To one of the four supports holding the rod is attached a metallic knob. Opposite, at an adjustable distance, is placed a second knob connected to a bent iron rod, one end of which is buried in the earth with the trestle. This rod also has a wire leading off to the network of earth wires belonging to the telegraph posts on the mountain. The author mentions the advisability of connecting the knobs by a fusible cut-out in order to tell, in case the rods are struck, which one has conducted the discharge, but he does not say that such cut-outs were actually used.

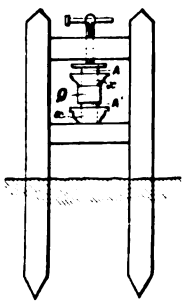
It is worthy of notice that since the rods were set up (*i.e.*, during the whole of the past year) *no lightning discharge whatever* has struck the mountain. Before their erection it was very frequently, indeed almost regularly, struck by lightning; consequently no results obtained with these rods can be given as yet.

The second part of the Paper is a discussion of the distribution of electricity on an insulated vertical conductor, when the potential of the air is assumed to fall at a constant rate as we ascend from the earth's surface. The object of this portion of the communication is to obtain a relation between the electrostatic potential of the conductor and the potential of the air at the upper end of it. If V_h be the potential of the air at the upper end of the conductor, and W_h that of the electricity induced on the conductor by the atmospheric potential V_h, we have, for the potential U of the rod,

$$U = \text{constant} = V_h + W_h = V_u + W_u,$$

where the suffix u refers to the lower end of the rod. If the fall of potential is constant $W_h = -W_u$, and, hence, $W_u = -\frac{V_h - V_u}{2}$.

We can regard the layer of air in contact with the earth as being at zero potential—*i.e.*, $V_u = 0$ in all cases. This gives us $U = \frac{1}{2} V_h$ and $W_h = -\frac{1}{2} V_h$. If the lower* end of the conductor be momentarily put to earth we get a different distribution—namely, $U = 0$, $W_u = 0$, $W_h = -V_h$.



The case of a conductor bearing a point or flame at one end is then considered. The term "aspiration" is used by the author to denote the action of such points or flames. The author shows that in the case of a conductor with strong aspiration at its upper end, and a similar weaker effect acting along its entire length, the potential of the conductor will be a little less than that of the air at its upper end, or $U < V_h$. Hence the insulated conductor ought to have nearly twice as high a potential when a flame burns at its upper end as it possesses when no aspirating apparatus is used, assuming always that the potential of the air falls at a constant rate on ascending from the earth's surface. Experiment always showed that the flame raises the potential of the conductor from 10 to 20 fold in the case of lightning rods such as those previously described. The author thinks that this discrepancy throws doubt upon the ordinary theory of the action of flames, and inclines to the belief that burning a flame at the end of a conductor is equivalent to increasing its length, the flame sucking down, as it were, the equipotential surfaces above it.

The rest of the communication contains a report of experiments with kites and balloons, to which long metallic wires were attached. Measurements were made of the strength of the current passing between these wires and the earth through a galvanometer. If the aspiration took place wholly at the upper end of the conductor—for example, by needles on the kite or balloon—the current would be proportional simply to U_h; but with an aspiration along the entire length (which always showed itself in the experiments) as well as that at the upper end, we have $J = \frac{1}{\sin\phi} \int_l^h V_x \alpha \, dx + A V_h$, where J is the current strength, ϕ the angle made by the metallic wire with the horizon, h the vertical height of the kite or balloon, and V_x the air potential at a vertical height x. A and α are constants depending on the rate at which aspiration takes place at the upper end of the wire and along its length respectively. Differentiating the equation, we obtain $\frac{dJ}{dh} = \frac{1}{\sin\phi} \alpha V_h + A \frac{dV_h}{dh}$, and, if a curve be made with the current strengths as ordinates and the vertical heights of the upper end (h) as abscissæ, we shall know that when the curve is convex to the axis of h the potential of the air falls at a constant or increasing rate as we go upwards from the earth's surface.

The wire used consisted of steel wires each of 0·27mm. diameter stranded together, and its weight was 32grms. per metre. The same wire was used with both kite and balloon. Its total length was 600 metres, and the length in use at any time was measured by means of coloured silk threads placed on the wire at distances of 10 metres apart. The largest current obtained in the experiments was about $9{\cdot}2 \times 10^{-6}$ amperes.

The results show that the rate of fall of potential generally increases with the height; but clouds have a very great influence upon the electrical distribution in the air. Cirrus clouds generally increase, and cumulostratus clouds decrease, the rate of fall of potential. When the clouds pass over the original distribution is restored. Rain tends very strongly to equalise the potential of the different layers of the atmosphere.

Some experiments made during a thunderstorm on an insulated lightning rod belonging to the University of Breslau are described at the end of the paper. The rod was connected to earth through a sensitive dead-beat galvanometer, and indicated a constant current from lightning rod to earth; this current was interrupted at every flash by a sudden kick generally in the opposite direction to the constant current, but sometimes in the same direction. No explanation of these phenomena has yet been discovered.

* The author considers the case of the upper end of the conductor being put to earth, and puts $W_h = 0$; but this is apparently an error of his. Whatever part of the conductor be put to earth we must obtain the same condition, $U = 0$.

LETTERS FOR LEARNERS AND UN-PROFESSIONAL READERS.

BY H. D. WILKINSON.

Section II.—Electro-Magnetic Fields.

(*Continued from page 45.*)

We may put the facts which were explained in our last paper very concisely in algebraical form by saying the magnetising force produced by a coil is proportional to

$$\text{Current} \times \frac{\text{total wire length}}{\text{coil diameter} \times \text{coil length}};$$

or the same law may be expressed in C.G.S. units by derivation from that already given in para. 130, viz.:—

$$\text{Magnetising force in C.G.S. units} = \frac{\text{ampere-turns}}{\text{coil length (centimetres)}} \times 1{\cdot}257,$$

where the constant 1·257 is the ratio $\frac{4\pi}{10}$, as explained in that paragraph. For, the number of turns in any coil is equal to the total length of wire, divided by the mean length per turn, and the mean length per turn is equal to the mean diameter of the coil multiplied by π (3·1416).

Therefore, cancelling out the constant π, we may write the above in the form

$$\text{Magnetising force in C.G.S. units} = \text{Amperes} \times \frac{\text{total wire length}}{\text{coil length} \times \text{coil diameter}} \times \frac{4}{10},$$

all measurements of length being in centimetres. From this it is clear that it is only when the *mean surface* of different size cylindrical coils is the same that we can compare the strengths of field produced by each by the product of the current and the length of wire; in other words, by the number of ampere-feet on each.

To return, however, to the magnetisation test. The number of turns per foot was 222·5, and the magnetising force was, therefore,

$$\text{Amperes} \times 222{\cdot}5,$$
$$= \cdot 18 \frac{D}{P} \times 222{\cdot}5 \text{ ampere-turns per foot.}$$

Reducing all galvanometer deflections (D) to position 32 (P = 32), as in the last example, and multiplying up, we have

$$\text{Ampere-turns per foot} = 1\tfrac{1}{4} D;$$

all that was necessary, therefore, was to add on to each deflection (reduced to 32) one-quarter of its value. These results

Digitized by Google

give the magnetising forces in ampere-turns per foot, due to the current in the coil; but we have an additional magnetising force constantly acting on the core, which must be taken account of. The core being vertical is acted upon by the vertical component of the earth's field. Taking the Kew Observatory data given in para. 110, and calculating out the value of the above, we have

Earth's vertical field = H × tangent of angle of dip.

The angle of dip or inclination is 67° 37′, and its tangent = 2·4282. Therefore

Vertical field = ·1810 × 2·4282 = ·4394 C.-G.-S. units.

This must be expressed in ampere-turns per foot, in order to add it to the magnetising forces due to the coil. We can do this from the expression

Field in C.-G.-S. units = 1·257 × ampere-turns per centimetre.

Now, 1 foot = 30·48 centimetres, and therefore the number of ampere-turns per centimetre is equal to

$$\frac{\text{ampere-turns per foot}}{30{\cdot}48}.$$

Substituting this value, and dividing out, we have

Ampere-turns per foot = field in C.-G.-S. units × $24\frac{1}{4}$.

The vertical force of the earth is, therefore, in this latitude equal to a magnetising force of

·4394 × $24\frac{1}{4}$ = 10·66 ampere-turns per foot,

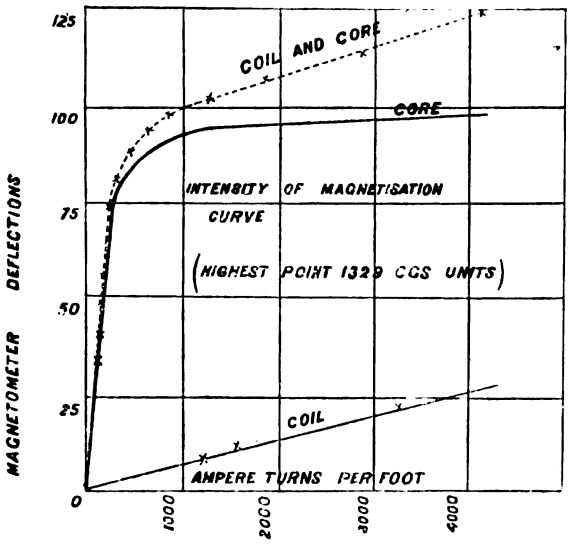


Fig. 118.

and is added to the magnetising forces set up by the coil to give the total magnetising force. We say *added*, because the current was purposely passed round the coil in the direction to cause the lower end of the core to become a north pole, and the earth's vertical force has the same effect. Had the current been in the other direction, the earth's force would have been subtracted. The usual method of dealing with this force is to neutralise it by winding another coil outside the first coil. This extra coil is usually of fine wire, and a current is passed through it just sufficient to set up a field exactly equal and opposite to that of the earth, and this current is kept on continuously during the magnetisation test, neutralising the vertical field.

The iron core, which was mechanically very soft and carefully annealed, was 90 centimetres long and 2·6 millimetres diameter. The length was, therefore, 346 times the diameter, and over Prof. Ewing's minimum limit for negligible demagnetising effect. In consequence of this it will be noticed that the rise in magnetisation is much more rapid at the commencement of the curve (Fig. 118) than with the former short iron core. The vertical ordinates of the two curves do not allow of comparison, since the cores are of different dimensions. This comparison must be made by the intensity of magnetisation, which can be calculated by the formula stated above. We must first find the value of m.

The distance (r) of the upper pole from the needle was 20 centimetres, and the length (l) of core being known (90 centimetres), the distance (R) of the lower pole can be found by

$$R = \sqrt{r^2 + l^2},$$

R being the hypothenuse of a right-angle triangle, of which r and l are the two other sides ("Euclid," I., 47). Working out these values we get for the denominator of the above expression ·9898, and for the numerator 72 tan a. We have, therefore, $m = 72{\cdot}73 \tan a$.

Now the sectional area of core is equal to

$$\frac{\pi d^2}{4} = {\cdot}7854 \times ({\cdot}26)^2 = {\cdot}053 \text{ sq. cms.},$$

and therefore the intensity of magnetisation is equal to

$$\frac{m}{a} = \frac{72{\cdot}73 \tan a}{{\cdot}053} = 1{,}370 \tan a.$$

We can now find the magnetisation at any given point on the curve. Take the highest point, viz., 97 divisions:—

I = 1,370 × ·97 = 1,329 C.-G.-S. units.

On switching off the current the magnetometer remained steady at 45 divisions; hence the residual magnetisation was

1,370 × ·45 = 616 C.-G.-S. units,

or 46 per cent. of the maximum magnetisation acquired. When the current is suddenly interrupted in this manner the residual magnetism is not so great as when the current is gradually reduced to zero. In soft annealed iron wires, whose relation between length and diameter was similar to the above, Prof. Ewing found the residual magnetism some 85 per cent. of the maximum; and as much as 90 and 93 per cent. in other specimens of soft iron ("Researches in Magnetism," *Phil. Trans.*, 1885).

136. *Comparison of Magnetisation Curves.*—The two curves obtained have been plotted with magnetometer deflections as

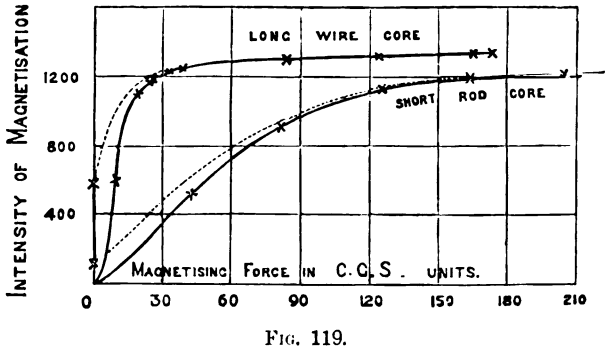

Fig. 119.

ordinates, but they cannot be compared by these deflections, as they were taken by different methods and with cores of different sectional area. We shall now compare them by plotting them with the intensities of magnetisation as ordinates, and at the same time express the magnetising force in C.-G.-S. units instead of ampere-turns per foot. For every 1,000 ampere-turns per foot we have 41·24 C.-G.-S. units (para. 134), and by inspection of each curve we find the magnetometer reading (tan a) corresponding to each 1,000 ampere-turns per foot and intermediate points. The intensity of magnetisation is derived from the magnetometer reading by

$$I = 1086 \tan a$$

in the first curve (para. 134), and by

$$I = 1370 \tan a$$

in the latter.

For example, in the latter curve we find by inspection that for 1,000 ampere-turns per foot (equal to 41·24 C.-G.-S. units) the deflection is 92, and therefore the magnetisation is 1370 × ·92 = 1260 C.-G.-S. units. Similarly, for 400 ampere turns per foot (equal to 16·5 C.-G.-S. units) the deflection is 80 and the magnetisation 1370 × ·8 = 1096 C.-G.-S. units. Taking several points this way, and plotting them as in Fig. 119, we are able to observe the relative magnetisation of the two cores. The main

Digitized by Google

points of comparison are the relative magnetisations acquired under any given magnetising force and the magnetic "retentiveness" of each core. It should be borne in mind that the top curve is that taken with a core whose dimensions satisfy the condition of "endlessness," and is a soft annealed wire, while the lower curve is that from a short iron rod of soft iron, but unannealed. The marked difference in the rise of the two curves is partly due to the slightly different nature of the iron, but *chiefly* due to the dimensions of the cores. This is very clearly shown by Prof. Ewing (to whose results the above are similar) in his experiments. He cut from the *same piece* of iron wire (of 1·8 millimetre diameter) different lengths, whose ratios of length to diameter varied from 50 to 300. The demagnetising effect and slow magnetisation were therefore proved to be due to the ends in short lengths.

In the above there was practically no demagnetising effect set up by the poles of the long wire core, and hence the full magnetising force of the coil could take effect upon it. With the short rod core, however, the poles caused a considerable reverse field of force, through the metal (para. 133) neutralising part of the field of the magnetising coil, and preventing the iron from becoming magnetised. This accounts for the very little residual magnetism left, being only about 9 per cent. of the maximum, for, when the current in the coil was reduced to zero the poles of the core exerted their reverse field, tending to neutralise the magnetism acquired. On the other hand, with the long wire core the poles could exert no demagnetising effect, and hence the iron, though softer, retained a much greater percentage of magnetism. These facts indicate clearly that magnetisation and residual magnetism depend as much on the shape as on the kind of iron. While it is always best to use soft iron to obtain the highest magnetisation for a given magnetising force, it is advisable in the construction of electro-magnets where the residual magnetism is to be minimised to make the core short and thick rather than long and thin. The cores of electro-magnets of fast-speed telegraph instruments have of late years been constructed more of the "squat" shape, this having been found to allow of more rapid signalling than the original tall, thin cores.

(To be continued.)

SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

At the meeting of this Society held yesterday (Thursday) evening, November 22, at the Institute of Civil Engineers, the President, Mr. E. Graves, in the chair, the following Paper was read:—

On a System of Electrical Distribution.

BY H. EDMUNDS.

It has been remarked that it is undesirable to bring a Paper of this kind before a scientific society on a subject which is only in its initial or untried stage. While there may be some justice in this remark, I think that in bringing this Paper before this Society to-night, I may have the opportunity of laying before you the results of certain experiments and actual work now extending over some 10 or 12 months, and of pointing out to you what have been the results of that work, and what the indications are with regard to its usefulness and extension.

In designing this system of Central Station Lighting it has been my endeavour to develop a plan of effectively and economically distributing the electric light over a given area, which should practically isolate each installation and make it independent and self-contained; which should obviate the use of objectionable machinery on the consumer's premises; which should ensure freedom from powerful and dangerous currents of electricity; which should provide a reliable supply of the electric current at all hours of the day or night; and which would enable a simple and readily understood form of meter to be used that would command the confidence of the consumer.

One of the great desiderata of a system of lighting is constant supply. It is not sufficient to supply the illuminant for a specified number of hours per day; what the householder wishes to have is a means by which he has always at hand a reliable source of light, capable of supplying all his requirements night and day. To ensure this it would be necessary either to have the generating machinery always at work during the whole twenty-four hours, or to employ some system of storage. Even if the machinery were constantly kept running, however, that would not render the constancy of the supply absolutely reliable, for the machinery might break down owing to accident or wear, and the district be deprived of light until the necessary repairs were made. Therefore it is essential that a reserve of electricity, independent of the generating plant, should be at hand, and such a reserve can only be obtained by the use of storage batteries.

The subject of electric lighting in conjunction with storage batteries is one that is receiving considerable attention from a good many engineers at the present time. The desirability of working with them has, I think, been admitted by most engineers for a long period, but the difficulty in connection with their use has been great. Among other things, the durability and efficiency of the battery itself has been more or less an unknown quantity, and this has caused people to hesitate before embarking upon any large amount of work dependent on them. It is hardly my province now to go into the history of the several methods which have been tried, but we may simply look on the two broad modes of working, viz., charging batteries in multiple, or charging them in series. As we do not in this system propose to charge in multiple we can leave that out of the question. We may therefore consider the mode that we are here adopting of charging batteries in series. It has been found to be most economical to use comparatively small conductors with suitable current and high electromotive force enabling one to carry the current over long distances from central stations, and to supply the current at different points on the line, as may be required for local work or use.

An opportunity for distributing current over a large area was presented to me some months ago, where a central station was available, suitable as to its position and size, but a long way from where it was intended to supply the bulk of the current for lighting purposes. It was necessary to consider the respective advantages of direct supply with low tension and high tension in conjunction with transformers. The former was out of the question on account of the distance, and the latter was at that time in disfavour, owing to several breakdowns and interruptions of the light to consumers having been reported in London. It was therefore deemed desirable to work in conjunction with a reserve, such as storage batteries in some form or other, and the idea occurred to me that a system might be developed which would practically be analogous to the transformer system, but using direct in lieu of alternating currents, and charging batteries in series with a constant current on one main line, rather than in parallel, and simply increasing the E.M.F. as the work increased and as the length of the line extended. This might be done in several ways, by dividing the line into sections, charging each portion for a good number of hours according to the probable demand, or by an arrangement for supplying current from the main to a portion of any group of cells less than the whole; but here a difficulty occurs, for it is most undesirable to be charging batteries as a whole or in part at the same time that they might be wanted for discharging. To obviate this, the batteries might be duplicated, so that one portion might be in the charging main and the other in the local. But this, again, is limited by the number charged in series at the same time. Besides this, the cells that have been charged have a large difference of potential when brought into the local, which causes a fluctuation of lights when such changes occur.

This brings us to the system which I have devised. Sets of accumulators are placed in groups at various points or sub-stations throughout the district to be lighted, and charged in sections from the central station. The secondary batteries at each sub-station are divided into four equal groups, with any convenient number in each group. For instance, we may have four sets of eight cells each, of which three sets, or 24 cells, will always be in connection with the lamp circuit, and supplying current locally to those houses which are in connection with the sub-station; while the fourth section will be in the main circuit, in series with the other sub-stations, being charged by the current from the central station. At short intervals the charged group is switched out of the main circuit into the supply, its place being taken by one of the discharged groups. In order that the three groups in the supply circuit shall be as far as possible in an equal state of charge, it is essential that the changes should take place at frequent intervals, otherwise one group would become highly charged while the other three are being nearly exhausted. Therefore, I have designed an apparatus by which each group is brought in succession into the charging circuit, charged for a short period—two minutes in actual practice—and then removed again into the supply circuit, in order that it may discharge itself. This apparatus I call a distributor.

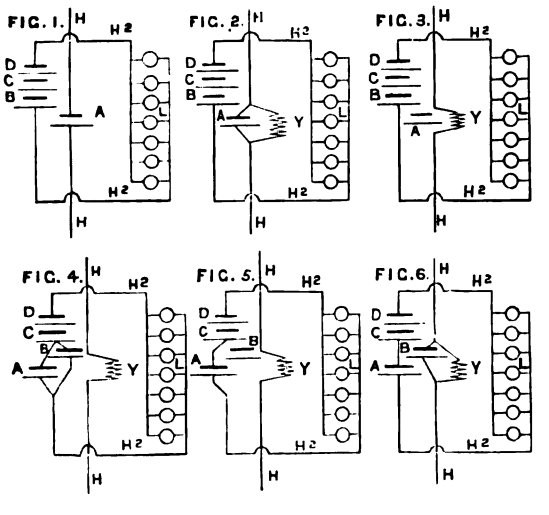
The operation of the distributor may be understood from the diagram on the following page. You will see that the four groups of cells are lettered A B C and D. H H is the main charging conductor, H 2 H 2 the branch conductor, and L the local installations. Y a resistance.

Digitized by Google

In Fig. 1 the battery A is shown in the main conductor being charged, while batteries B, C, and D are connected together in series, discharging locally. In Fig. 2 the resistance Y is connected in parallel with the battery A, thus giving a by-path for the main current, which now divides itself between the two circuits, viz., the resistance and the battery. In Fig. 3 the battery A is now disconnected from the charging main, the resistance Y carrying the whole of the current, and maintaining the continuity of the charging circuit. You will observe that battery A is now free, and is to be removed to the local circuit. In Fig. 4 this is effected by coupling it in parallel with battery B. You will observe here that the two negative poles of the batteries A and B are coupled together to the local negative, while their positives are coupled together to the negative of local C. We have thus been enabled to introduce A into the local circuit without causing any alteration in the E.M.F. of the series or censequent fluctuations in the local circuit.

We can now, as in Fig. 5, isolate the battery B from the local battery, A having taken place, maintaining the continuity of the local. Battery B is now connected with the main in parallel with resistance Y, as in Fig. 6. Resistance Y is then cut out, leaving battery B to receive the full charging current of the main H H, it practically being the substitute for battery A, as in Fig. 1.

These cycles of changes are essential to the efficient carrying out of this system, for we must guard against interrupting the main charging circuit, because of other work going on in the circuit at the same time in series with the battery under consideration. We must also be careful at no time to alter or fluctuate the pressure of the local batteries. We must also at no time have the charging main in contact with the local batteries, as this might cause a variation in their pressure, or in an extended system have a tendency to leaking through the local to earth, with its attendant dangers. You will see, therefore, that by carrying out this cycle we ensure all the requisite conditions.



In practice this cycle of changes takes piace at intervals of about every two minutes, the batteries A B C and D receiving their increments of charge, A for two minutes, B for two minutes, C the same, and D the same; so that in eight minutes each of the cells will have received two minutes' charge. The charge now proceeds in the reverse direction from D to A; thus the cycle is A B C D D C B A, &c.

Although the process of describing in detail the changes which are shown in the diagrams, and which complete one cycle, have been somewhat lengthy, it must not be supposed that the actual change in the mechanical-electrical actions of the distributor which bring about this result are of any protracted period of time. If so, the value of the system would be neutralised. The actual time occupied is less than one second, so that in 24 hours the distributor instrument is only actually under movement for 12 minutes. This practically consumes very little time, and prevents any appreciable wear of the moving parts.

But it will be observed that in 24 hours we only charge a group of cells, as a whole, with a six hours' current. On the other hand, we only want one-third of the charging potential in the main. This enables us to do a given amount of work with one-third of the plant, and one-third of the pressure at the charging station, compared with what would be required if we were doing the same amount of work by a direct system. This is very important. The cells are kept in much better condition by continually receiving fresh increments of charge, and having periods of rest from discharge. Also, the loss due to difference of potential between the charging and discharging current is minimised, it being found in practice that we can continue charging the cell to its maximum capacity with a mean voltage of 2·25, instead of 2·5 per cell, as is required where cells are charged continuously. This, on a large scale, is a considerable element of economy when there are a large number of cells in the charging main. Besides this, we find that an approximately constant potential on the local circuit enables us to run lamps at a higher efficiency without the risk of rupture due to sudden rise of pressure, and, so far as we can judge, the current supplied from the dynamos at the central station is 70 amperes, this being the amount by which the large-sized E.P.S. cells are best charged. The voltage of the dynamo varies according to the work at any one time on the line, and the current is maintained constant at all times. A simple mode of ensuring these results has been obtained by using an ordinary series dynamo, whose field is excited from a separate source, by batteries, for example, incidentally charged from the main, and the speed of the dynamo is varied in accordance with the variations of the work or external resistance of the circuit. I find that by proportioning the size of the engine to the dynamo it has to operate we need only keep a constant pressure on our engine to ensure the regulation being entirely automatic. We have been able to dispense with electric regulators of all kinds in the station, for the dynamo practically regulates the speed of the engine, only going at a given speed in order to produce the requisite E.M.F. to supply the 70-ampere current through the whole of the work in circuit at any time. Should batteries be cut out of circuit the result is that the resistance is lessened, upon which the volume of current is increased. This immediately acts like a brake on the engine, causing it to run at a less speed until it has accommodated its speed to the normal 70 amperes, provided that meanwhile the steam pressure in the cylinder has been kept constant. This can conveniently be done by means of an ordinary steam pressure regulator. Should, however, more work be included in the circuit, the result will be that the current will suddenly fall, freeing the breaking effect on the engine, causing it to respond and run at a higher speed, until such time as it has brought up the current to the normal of 70, of course demanding more steam, which the stoker must look out for. In this way it is only necessary, by means of a speed counter, to take the revolutions of the engine or dynamo of the station at any time as being an exact index of the work going on at that time, and, as the work increases when the speed of any one engine gets up to its mechanical limit of safety, two or more machines are then brought in series with the others, and, acting in the manner already described, keep this constant current with its proper potential always on the main circuit. Having a time apparatus to effect the changes described in the battery, and a constant current in the main, it is only necessary to bring these two together, as the tension on the batteries is practically the same, in order to form a very efficient and simple meter, which, having only to deal with the current supplied in the charging, has not to differentiate and take account of the varying amounts used in the discharge.

Of course, it may be said that a system of this kind is essentially dependent on the mechanical details used for carrying the same into effect, and here actual practice has been of very great use to me. The Cadogan Electric Light Company, of Chelsea, having adopted this system, has enabled me to see actually what such shortcomings were. The apparatus I have here to-night is of the kind that has been in use there, and like all first forms, has not performed as well in practice as it did with the care and attention it received in the laboratory.

The apparatus here consists of a powerful electro-magnet driving a set of cams, which operate four levers, each lever carrying a full set of combination of contacts for each of the groups of batteries in use at one time. This reciprocating lever arrangement, however, has shown a serious difficulty, for the levers have occasionally wedged themselves so tightly that the electro-magnet could not draw them out, or, on the other hand, have proved too slack, so that insufficient contact was made, and sparking and heating caused in the apparatus. All this, I am glad to say, has been got over by the substitution of a rotary for a reciprocal motion, and now I can show you an improved form of apparatus, which is doing the work here this evening, which carries out all the requirements of this system in a much simpler manner. When any group of cells are sufficiently charged so that they ought to be disconnected from the charging main, an arrangement called a voltage regulator is brought into use. This causes the batteries to be disconnected from the main, and to remain disconnected until such time as they are discharged sufficiently to reduce their E.M.F. to a lower level, when the apparatus automatically causes the battery to be again put into the charging main. It will be obvious that such a system as this is is sufficiently elastic by varying the number of cells to give practically any potential that may be demanded, and can therefore comply with all kinds of requirements for lighting, arc or incandescent, or supplying current for other purposes. It is very desirable not to have too great a variety of pressures, and therefore in houses where but a small amount is demanded it is best to put down a plant of sufficient size to supply several together from one distributor, thus forming a

Digitized by Google

small station, it being, however, always desirable to have the same as near as possible to the point of consumption, and much cheaper to carry our charging main there than to have the local discharge mains. It is convenient not to have such stations too large, or at too great a distance from their work. For suburban or scattered lighting this system is very useful, as only one main is required of, say, three-eighths of an inch cross-section, which can be conveniently carried overhead or underground.

In this Paper I have not gone into the question of cost, but from the experience we have had think that such a system compares most favourably in this respect with any of the direct or alternating-current methods, and I hope it will prove a means of supplying that great demand which all engineers feel is now upon us.

OUR SUPPLEMENTS.

THE SOUTH AFRICAN CABLES AND THE ELECTRIC LIGHT AT SOUAKIM.

We publish as supplements this week a map showing the projected extension of telegraphic communication to the Cape of Good Hope, and a plan of Suakim, illustrating the value of the electric light in warfare.

It is now about nine years since South Africa was connected telegraphically by means of a line of cables on the East Coast of Africa from Aden to Durban, with stations at Zanzibar, Mozambique, and Delagoa Bay. More recently cables were laid on the West Coast, starting from St. Vincent, by the African Direct and West African Telegraph Companies, which carried the communication as far south as Loando. At a meeting of the shareholders of the Eastern and South African Company, held yesterday, authority was given to raise the necessary capital to lay a cable which should have been represented on the map by a *dotted* line, from Cape Town to Mossamedes, Benguela, and St. Paul de Loando, where it will join the existing cables, thus placing the Cape of Good Hope in direct submarine telegraphic communication with this country, and affording an alternative route to that on the East Coast.

The fact that in the space of ten years Africa should be almost completely encircled by the telegraph affords a striking example of the rapidity with which submarine communication is being extended. It may be said that the eyes of all Europe are turned to the Dark Continent, and that all the nations are interested in its development. In view of the immense possibilities of its future it is interesting to note the commercial enterprise which has connected telegraphically all the important points on its coast with the rest of the world at a time when only an infinitesimal portion of its immense territory has been brought under the influence of civilisation.

The state of affairs at Suakim is an instance of the "surf which marks the edge of the advancing wave of civilisation," as Lord Salisbury said the other day.

A correspondent on the spot says: "There is not the slightest doubt that leaving Suakim without the protection of men-of-war, after H.M.S. 'Dolphin' and 'Albacore' cleared out on the 17th July, owing to heat and sickness, and allowing the electric light to fall into disuse, are the causes of the dilemma we are now in. Earthworks sprang up over night as if by magic, which could not have happened had the electric light been kept in order.

"After a cricket match the other evening the sentry telephoned in 'Tent gradually moving westward,' and before things could be made clear the tent (which had been left on the cricket ground), and under which the rebels had got and cut the ropes whilst keeping it open by their numbers, was carried bodily away under the very noses of the fort gunners, who could not believe their eyes."

It will be remembered by readers of the daily papers that the light on Quarantine Island was repaired by the staff of the Eastern Telegraph Company's ss. "John Pender," and that on Shaata Gate- which is the more important, being 1,500 yards nearer the trenches—by the officers of the same company's ss. "Electra.'

The plan which we give is from a sketch by the electrician of the latter vessel.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *November 10th*, 1888.

The American Gas Light Association has recently held its 16th annual meeting at Toronto, Canada, where it was warmly received by the gas interests of the Dominion. In his opening address, the president, Mr. T. Turner, of Charleston, South Carolina, made an interesting reference to the relations between gas and electric lighting. In congratulating the members on the general and almost unprecedented prosperity of the business during the past year, he took occasion to ask the question whether any explanation of this large increase in the quantity of gas called for could be given, particularly in view of the fact that the electric light is now a far from inconsiderable portion of the light used in large cities. He answered his own interrogation with several reasons. The first of these was the natural tendency of all the consumers towards the use of more light; the second was the low price at which gas was now offered and sold; a third, and main reason, was that the application and use of the electric light had the effect of compelling people to use more light. He thought they ought to be generous and give the electric light credit for its assistance in increasing the sales of gas. Some gas companies and gas engineers, he remarked, had pursued the policy of fighting the electric light. "This," said Mr. Turner, "I regard as a mistaken policy. No gas company or gas manager can afford to stand in the way of the development and march of improvements of any kind. Development and improvement are the order of the day in this age. The world must go forward, onward and upward toward perfection, and the man or men who would endeavour to stop the wheel of progress does not comprehend the tendency or drift of things in the age in which we live. The electric light has its advantages; let us acknowledge them. It also has its defects, which are ample enough to interfere with its progress to that extent." In view of the persistent experiment and research for the last 10 years in the development of the science of electricity, as applied to the production of artificial light, the only inference that could be formed was that illuminating gas had certain qualities which insured its continued use for an indefinite time. Mr. Turner admitted that the market price of gas stocks had at times been lowered by the progress that the electric light had made and is making; but he held that the business, as a whole, had not suffered. Although such were his opinions on the subject, Mr. Turner was not entirely in favour of the policy of amalgamating the business of gas lighting with that of electric lighting. He could not see why gas companies should engage in electric lighting any more than they should attempt to handle kerosene oil and candles. He doubted the ability of a man to manage two such different and dissimilar businesses, and thought that the combination plan must result in the neglect of the one interest or the other. In some instances advantages might accrue from consolidation; but still he thought that the attempt at monopoly was of dubious wisdom. Mr. Turner has evidently given serious and mature thought to the subject; but we may judge, from what goes on around us, that gas managers generally do not agree with him. A great many gas companies are in the business of supplying the electric light, and their number is daily added to, while, in a great many other instances, the combination of the two interests under one management, or under the control of the same capital, has been effected.

American electricians have been very much interested in the accounts which have reached here of the revival of electric lighting in England, and of the movement now on foot to undertake the supply of current on a larger scale. The news from London, both in regard to the purchase of Westinghouse apparatus and the starting of work on the two-million light station at Deptford, has caused a great deal of discussion. When the latter project is actually carried out it will be time, perhaps, to discuss it on its merits; but the general idea here seems to be that it is hardly worth while to tie up so much generating capacity in one unit, greater safety and better results being attained with a little more subdivision. I do not think

Digitized by Google

that there is any likelihood of any station of that size being built yet awhile in this country. In this city, for example, if any such plan as the supply of two million lights were entertained, it would probably be decided to divide the city into districts, and to establish a station for each. This is virtually what the Edison Company has done with its system of direct current, and I do not think there would be much departure from that practice even with the alternating current. Our arc lighting companies, for example, have found it best, from practical experience, to divide up their capacity into three or four stations, each of which looks after its own section of the city, and can, in case of emergency, throw its current into the circuits of the other stations, should those stations happen to be cut off or disabled in any way.

Montreal, Canada, is promised a telephone rate war. A new corporation, called the Federal Telephone Company, has been preparing for business for some time past, getting up its poles and wires in spite of a good deal of opposition. It is now supposed that they will be ready some time in the spring, but in the meanwhile the old Bell Telephone Company of Canada has given notice that it will cut its subscribers' rates in Montreal at the beginning of the new year to $25 per annum. The former rate of the company was $50. A *pro rata* rebate to the present subscribers is to be made by the extension of their leases. This is intended to destroy the effect of the tempting offer made by the new competing Federal Company, which proposes to do business at a rate of $35 per annum. It is thought in some quarters that the new company will find it rather uphill work under such a state of affairs, but we may at least look for a very lively competition.

The Thomson-Houston Electric Company have just begun work on an electric railway at Topeka, Kansas. The road will be 14 miles in length, will have about 30 or 40 cars, and will cost somewhere in the neighbourhood of from £40,000 to £45,000. This plant, it is said, will be the largest in the world, exceeding even that at Richmond. The overhead system will be used. The generators will be run by two Corliss engines of a total of 700 horse-power, with boilers of 800 horse-power. A special new station is to be built for the work, 85ft. by 100ft., two stories high, brick and stone. Each car will carry two motors. Work is to be pushed ahead at once in this installation, and it is expected that the road will be running by January 1. It will be seen from this that we are well into the era of large electric roads. Only a few short months ago a great many people were disputing the ability of the electrical engineers to operate more than one or two cars on a road, but now we have such large roads as those at Richmond, Scranton, Dayton, Akron, and Appleton, and larger new ones like those at Topeka, Boston, Cleveland, and Omaha.

I believe I have alluded before in this letter to the ravages of the yellow fever at Jacksonsville, Fa., and to the gallant stand made there by the staff of the telegraph and telephone companies. A great deal of quiet courage has been shown, and the officers and operators have stood manfully to their posts amid all the terrors of the plague, and under the burden of tremendous overwork. The New York *Electrical Engineer* of this month mentions one instance of a young girl, Miss Mamie Davis, who held her post in the telephone exchange when left entirely alone for a time during the epidemic. At one period everybody was down with the fever excepting herself; but there she sat at the board from morning till night, snatching hurried mouthfuls of food between the calls for doctors, undertakers and ambulances, and never flinching or thinking she was doing anything heroic or out of the way. I trust and believe that the little heroine will be remembered by the company in some substantial manner, and I take this opportunity of placing the homage of one admirer at her feet.

Another instance of the gallant spirit of our Southern folk is seen in the fact that the Jacksonville Electric Light Company, in spite of all the depression of business from the epidemic, has gone ahead with plans for enlarging its plant. Perhaps they have been stimulated to this by the new theory, just advanced, that the microbes flourish in darkness, and that one of the best means for their extirpation would be an overwhelming flood of light such as is given out by the electric arc.

The telephone companies have been very busy this week handling the returns of the Presidential and State Elections. I do not think, however, that the total of the matter sent and received will equal that of 1884. At that time the general result of the vote was in doubt for some days, and there was consequently an unstinted use of the wires by the newspapers. This year the result was practically decided on the same night, and the only point which has interested the people since has been the size of the majorities; so that the necessity for the use of the telegraph on a large scale has not been very marked, except in the supply of special returns on election night. A new feature of the work was the receipt on Tuesday night, from various parts of New York State, of long-distance telephone despatches; and the announcements were so labelled on the bulletin board. I have not seen this use of the service made so prominent before, and I have no doubt that it acted as a good advertisement of the new convenience to the thousands of people who assembled in breathless excitement all night long in front of the newspaper offices, at the political headquarters, and underneath the sheets of the stereopticon.

I suppose you are aware by this time that the election has gone against Mr. Cleveland, and has therefore given a setback to the movement for tariff reform. As a general thing this is regarded with favour in electrical circles, although opinion is by no means unanimous on the subject. One of the incidents of the election has been the defeat of Mr. Hewitt, as mayor of this city for a second term. Mr. Hewitt, as you may remember, has been the ally of the local arc light companies in their opposition to the plans of the Subway Board. He announced that until he saw a thoroughly practicable and feasible underground system he could not be a party to compelling the companies to take their wires off the poles; and he has been as good as his word. The result has been a state of affairs not unlike a deadlock, the Subway Board being checked in its efforts by the opposition of the mayor, and the apathy of the officials working under his jurisdiction. Now, however, the scene changes. The new mayor in the pre-election declarations that outlined his policy pledged himself to active work in the removal of the wires. This incoming mayor, Mr. Grant, is the nominee of Tammany Hall, our big Democratic club, which has been successful in returning its candidates throughout the city for every office for which they were nominated; and now that they are deprived of the support of the mayor the electric light companies are going to have a rather hard time of it in being subject to the tender mercies of Tammany Hall and its cohorts. Mr. Grant, personally, is regarded as a clean man, in the political sense, but he is not stronger than his party. It may not be unworthy of mention that Mr. Ed. Stokes, who has had an interest in the affairs of the Postal Telegraph Company, the only rival of the Western Union, is popularly regarded as one of the powers behind the throne in Tammany Hall.

CORRESPONDENCE.

THE ELECTRO-MAGNETIC EFFECT OF A MOVING CHARGE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The question raised by S. P. Thompson (p. 54, Nov. 16) as to whether the motion of an uncharged dielectric through a field of electric force produces magnetic effects must, I think, be undoubtedly answered in the affirmative. As the distribution of displacement varies, its time-variation is the electric current, with determinable magnetic force to match. When the speed of motion is a small fraction of that of light we may regard the displacement as having at every moment its proper steady distribution, so that there is no difficulty in estimating the magnetic effects, except, it may be, of a merely mathematical character. For instance, the case of a sphere moving in a field which would be uniform were the sphere absent, is readily attacked, and does perfectly well to illustrate the general nature of the action.

Digitized by Google

But if the moved dielectric have the same electric permittivity as the surrounding medium, so that there is no difference made in the steady distribution, the question which may be now raised as to the possible production of transient disturbances is one to which the above theory does not present any immediate answer. I believe that the body will be magnetised transversely to the electric displacement and the velocity.

Another question, somewhat connected, is contained in Poynting's suggestion (in letter to Lodge, p. 829, Vol. XXI.) that electric displacement may possibly be produced without magnetic force by the agency of pyroelectricity. But, whatever the agency, it would, I conceive, be a new fact—quite outside Maxwell's theory legitimately developed. We may have subsidence of electric displacement without magnetic force; but I cannot see any way to produce it.

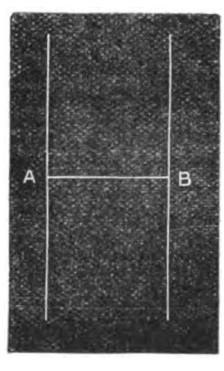
But the main subject of this communication is the electromagnetic effect of a moving charge. That a moving charge is equivalent to an electric current element is undoubted, and to call it a convection current [surely not "convexion"], as S. P. Thompson does, seems reasonable. The true current has three components, thus,

$$\text{curl } \mathbf{H} = 4\pi(\mathbf{C} + \dot{\mathbf{D}} + \rho\mathbf{u}),$$

where $\mathbf{H}$ is the magnetic force, $\mathbf{C}$ the conduction current, $\mathbf{D}$ the displacement, and ρ the volume-density of electrification moving with velocity $\mathbf{u}$. The addition of the term $\rho\mathbf{u}$ is, I presume, the extension made by Fitzgerald to which S. P. Thompson refers. At any rate I can at present see no other.

There are several ways of arriving at the conclusion that a moving charge must be regarded as an electric current; but, when that is admitted, we are very far from knowing what its magnetic effect is. No cut-and-dried statement of it can be made, because it varies according to circumstances. The magnetic field, whatever it be in a given case, is not that of a current element (supposing the charge to be at a point), for that is anti-Maxwellian, but is that of the actual system of electric current, which is variable.

Thus, in the case of motion at a speed which is a small fraction of that of light, the magnetic field (as found by J. J. Thomson) is the same as that of Ampère's current-element represented by $\rho\mathbf{u}$; that is, a current-element whose direction is that of $\mathbf{u}$ and whose moment is ρu, if u is the tensor of $\mathbf{u}$ (understanding by "moment," current density × volume); but the true current to correspond bears the same relation to the current-element as the induction of an elementary magnet bears to its magnetic moment. The magnetic energy due to the motion of a charge q upon a sphere of radius a in a medium of inductivity μ, at a speed u, which is only a very small fraction of that of light, is expressed by $\frac{1}{3}\mu q^2 u^2/a$. But if the speed be not a small fraction of that of light, the result is very different. Increasing the speed of the charge causes not merely greater magnetic force but changes its distribution altogether, and with it that of the electric field. It is no use discussing the potential. There is not one. The magnetic field tends to concentrate itself towards the equatorial plane, or plane through the charge perpendicular to the line of motion. When the speed equals that of light itself this process is complete, and the result is simply a plane wave (electro-magnetic).



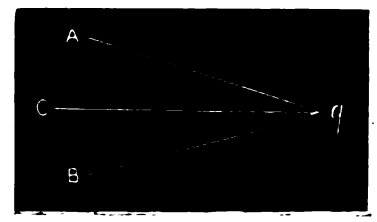
Since a charge at a point gives infinite values, it is more convenient to distribute it. Let it be, first, of linear density q along a straight line AB, moving in its own line at the speed of light. Then the field is contained between the parallel planes through A and B perpendicular to AB, and is completely given by

$$E/\mu v = H = 2qu/r,$$

where E and H are the intensities of the electric and magnetic forces at distance r from AB. The lines of $\mathbf{E}$ radiate uniformly from AB in all directions parallel to the planes; those of $\mathbf{H}$ are everywhere perpendicular to those of $\mathbf{E}$, or are circles centred upon AB. Outside this electro-magnetic wave there is no disturbance. I should remark that the above is a description of the *exact* solution. It is, of course, nothing like the supposed field of a current element AB.

To still further realise, we may substitute a cylindrical distribution for the linear and then, again, terminate the lines of $\mathbf{E}$ on another cylindrical surface between the bounding planes. To find the resulting distributions of $\mathbf{E}$ and $\mathbf{H}$ (always perpendicular) may be done by super-imposition of the elementary solutions, or by solving a bi-dimensional problem in a well-known manner.

Those who are acquainted with my Papers in this journal will recognise that what we have arrived at is simply the elementary plane wave travelling along a non-distortional circuit. All roads lead to Rome!



Returning to the case of a charge q at a point moving through a dielectric, if the speed of motion exceed that of light, the disturbances are wholly left behind the charge, and are confined within a cone, AqB. This charge is at the apex, moving from left to right along Cq. The semi-angle, θ, of the cone, or the angle AqC, is given by

$$\sin\theta = v/u,$$

where v is the speed of light, and u that of the charge. The magnetic lines are circles round the axis, or line of motion. The displacement is away from q, of course, and of total amount q, but not uniformly distributed within the cone. The electric current is towards q in the inner part of the cone, and away from q in the outer.

It will be seen that the electric stress tends to pull the charge back. Therefore, applied force on q in direction Cq is required to keep up the motion. Its activity is accounted for by the continuous addition at a uniform rate which is being made to the electric and magnetic energies at q. For the motion at the wave front, at any point on Aq or Bq, is perpendicularly outward, not towards q. Whilst the cone is thus expanding all over, the forward motion of q continually renews the apex, and keeps the shape unchanged.

Steady motion alone is assumed.

To avoid misconception I should remark that this is not in any way an account of what would happen if a charge were impelled to move through the ether at a speed several times that of light, about which I know nothing; but an account of what would happen if Maxwell's theory of the dielectric kept true under the circumstances, and if I have not misinterpreted it.—Yours, &c.,

OLIVER HEAVISIDE.

November 18, 1888.

THE SPRAGUE MOTORS AT RICHMOND AND MR. ALBION SNELL'S CRITICISM.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Your issue of August 31st contained a Paper entitled, "The Sprague Motors at Richmond, Va.," by Albion T. Snell, which, while deprecating any intent of captious criticism, contains at once, with some interesting comments, several most un-

Digitized by Google

justifiable conclusions, which a fuller knowledge of the subject would have led him to avoid. I do not think the question whether the English electrical engineers have anything to fear from their brethren on this side of the Atlantic is an important one in this connection. Whatever the self-complacent conclusions to which Mr. Snell may have arrived, it is quite within the possibilities that all competent electrical engineers can design motors of equal electrical and mechanical efficiency where no limitations are put upon them; but what is a matter of more importance is how far the purely electrical deductions of the school or laboratory shall be subordinated to mechanical and commercial considerations, and if we are to judge by the relative advances made in England and the United States, I think the credit can be claimed for the Americans of dealing with these questions in a more matter-of-fact and pertinent manner. This may be acknowledged after due weight is given to the difference between English and American public spirit and enterprise, which same difference may possibly exist between electrical engineers of the two nationalities.

Novelty alone does not win in the United States, nor would a knowledge of the business done confirm the opinion that liberality of public spirit is the chief reason of success. One thing seems to be forgotten by an Englishman when discussing things American, and that is the fact that a newly-developing business of special character is carried on with New York as a centre in places which may be as far away as Boston or Halifax, Smyrna or Trieste, or Constantinople is from London, and that it may take seven days of continuous travel to reach a point where work is being progressed. Does a liberal public spirit, may I ask, guarantee the success of an enterprise under such conditions? If so, the public spirit of our people in this widely-diversified country is, indeed, liberal.

Turning to Mr. Snell's Paper, I find that he asks concerning certain curves published in a Paper read before the American Institute of Electrical Engineers, "Why were they ever published in their present form?" especially in view of the omission of allowances for material friction, self-induction, &c. These omissions being so apparent, it would seem that Mr. Snell's statement concerning them, that they are theoretical curves, might have been accepted as a fair explanation and so treated. The curves are not, however, entirely theoretical. They are based partly upon experiments, partly on theory, and are useful for pointing out in a general way the approximate shape of certain characteristic curves of a motor under one condition of working, and some new uses to which such curves, assuming them to be correct, may be put. They have the same value that a theoretical steam diagram may have, and serve a purpose which is just as well attained for the layman as perfectly accurate ones, and, in fact, they must first be understood before the more accurate and elaborate curves can be fairly considered. If a strictly correct representation of a machine is to be made, much more numerous curves must be laid down than those suggested by Mr. Snell, and should be given in comparison with the theoretical ones. Many of his remarks are, however, interesting and to the point, and a more useful analysis of the motor would have been given had his method been adopted in conjunction with my own, and hence I may be permitted to make some comments on his criticism.

Referring to the diagram published in your issue of Aug. 31, the curve O A gives the average electromotive force of a particular armature when running at a determined speed with an increasing and decreasing field and for constant and periodic work, and takes into account self-induction (which lowers the curve) and the distortions set up by the armature current which would exist with the field coils in a particular relation; it can be obtained no matter how the field coils are excited so long as the ampere turns correspond and are proportional to the armature current. This curve is, of course, a variable one when a large number of machines are built and when the conditions of actual work are considered. Its flattening is due rather to scantiness of wrought iron, and the use of cast iron, in the magnetic circuit, and the length of the latter, as well as to the distortion set up by the armature—faults which commercial demands are largely responsible for.

The line of motor electric motive force in terms of the resistance and current should, of course, be slightly concave, because of the self-induction of the coils leaving the brushes, or it could be made straight by varying the graphic unit of current.

We would have in practice $C = \frac{E - (e + e')}{R}$, where e' is the induction increment, its value depending upon the turns of the wire and the current.

The speed curve in terms of the current E D C does not in practice for these particular machines depart very seriously from that given within the actual limits of working, the speeds being, in one of the stock machines recently tested, and probably with fair accuracy, as follows:—

Amperes.	10	15	20	25	30
Sprague curve ...	1,167	900	775	690	630
Actual	1,185	946	806	687	603
Snell's curve* ...	967	860	667	600	540

being thus greater than my curve readings when less than 25 amperes, and less than these when greater than 25.

As regards the work curve, it is an ordinary practice in rough work to plot it for horse-power $= \frac{Ce}{800}$ instead of $\frac{Ce}{746}$, and then to allow for any interesting work curve an increase of 10 per cent. for material friction.

Absolute accuracy is not quite practicable except in a laboratory. The expression horse-power $= \frac{Ce}{746}$ is a true one, but it does not of course represent the brake horse-power, since it includes useful work: air, commutator, journal, and gearing friction; air fanning; work expended in generating eddying currents in the armature discs and binding bands, and in the pole pieces; the work of overcoming self-induction in the coils leaving the brushes; and energy expended in short-circuited coils. The aggregate of the prejudicial classes of work would nearly bring the curve O F C to Snell's curve 4; but the ultimate reading of the characteristics of an intersection would be about the same as would be afforded by plotting the work curve as horse-power $= \frac{Ce}{800}$, and allowing an increase of 10 per cent. in the equation for car work, as was done; the former method is, of course, a truer indication.

The curve O D G, giving the work of the motor in terms of its own speed, would, if plotted from E D C, corrected for self-induction, and O F C, corrected for material losses, be perfectly accurate, because it is simply based upon the facts indicated by these curves, and is plotted from transferred co-ordinates. Similar remarks are true concerning the curves of torsional effort.

Mr. Snell makes a most serious mistake when he assumes that these machines are designed to be run with the greatest normal output with half the maximum current—in other words, at about 14·5 horse-power, and with over 50 amperes of current; and he points out the great heat loss which would exist under such circumstances.

He asks, "How long would a motor run with a furnace inside it?" and immediately afterwards says, "and note the car speed for this current is about three miles per hour, and so this must occur frequently;" he then naively adds, "well, the writer cannot explain this, &c." With the consciousness of this lack of explanation, because of the knowledge that the assumption is entirely untenable, Mr. Snell should, it seems, have hesitated before jumping to hasty conclusions. True, it is said that the motors can for a short time work up to double their normal capacity, and considering the fact the line potential can be readily raised to 500 volts, and that for a few seconds, under some very abnormal conditions, such as one motor being broken down on a very heavy grade, or with a car off the track, a motor may be put under a most exceptional strain, the remark is fairly true; but the assumption of Mr. Snell is that because the car must be often running at three miles per hour this over-load must be a normal condition of affairs. While I did not explain any particular method of governing these machines, I did say that they were commutated; and the key to the explanation lies in the difference between English and my practice in street car motor government.

* It is perhaps desirable that we should remark that Mr. Snell's curve is itself an "actual" curve.—Ed. *E.*

Digitized by Google

One of the things which are concerned is the total efficiency of the car circuit, which circuit includes the motors and the governing devices; but this is not all. The speed at which, with a total determined car circuit efficiency, series motors will run is of equal importance. There are three general methods of controlling motors: one (and it seems Mr. Snell's favourite) is to make use of external resistance, leaving the motor circuit undisturbed; another is to make use of both the external resistance and certain changes in the motor circuits; a third is to govern the motors entirely by variations in the arrangement of the field coils.

I have used all methods, but the last is characteristic of the Richmond machines. Their fields are wound with three sets of coils, varying in the number of turns, the cross-section of the wire, and the resistance; these are connected with a switch, so that when the motor is thrown into circuit the field coils are all in series and have a definite high resistance. The coils are then progressively commutated till they are finally thrown into multiple circuit, and have a resistance of only one-ninth that first existing. In this way a fairly constant field may be maintained for currents varying 300 per cent., and the motor be made to meet any required conditions; while for any particular arrangement of the coils many of the advantages and characteristics of the simple series motor are retained. The great advantage of this method is that with any light load and with a given total efficiency of the car circuit the motor will run at a much lower and constant speed than if made with a fixed series field resistance and governed by a resistance coil; part of this governing can be accomplished by changing the armature circuits, but this method has such disadvantages that it was after a long trial in Richmond finally discarded.

As regard the Richmond motors, they are by no means perfect machines, and they have been called upon to do an abnormal amount of work, much more than was ever anticipated; the normal maximum load should be about 7½ horse-power including friction, and they will develop this with about 18 amperes of current on a 400-volt circuit. The ratio of the motor electromotive force to the electromotive force existing at the terminals of the armature is then about 93 per cent. The average current through the machines is not over five to eight amperes. When we consider that the machines have to be built to work up to 500 volts, if necessary, with the base frame in circuit and hence necessarily well insulated, and in addition must be able to stand instant reversal with a heavy load on a 10 per cent. down grade, and were, furthermore, built to meet certain demands in regard to space, cost, &c., I have yet to hear of an English machine to meet like conditions more successfully.

Mr. Snell says that English practice would be to make a machine of equal capacity of about ·65 ohm resistance; but it may be a pertinent inquiry to ask *what* English machine, built for like conditions and service, to meet the same commercial demands and governed in the same way, and with a normal maximum brake load of 7½ horse-power on a 400-volt circuit, is built to have a total resistance of motor and regulating apparatus of ·65 ohm? There is none. On the other hand, on the same page Mr. Snell says: "In ordinary English practice a motor absorbing 50 amperes and, say, 100 volts, and running an eight-ton car at about three miles per hour, would have an internal resistance of ·25 ohm, &c." There seems to be some confusion in the unquoted part of this statement; but if the motor has ·25 ohm resistance on a 100-volt circuit, it will measure, because of the increased space taken up by insulation, somewhere about 4·5 ohms on a 400-volt circuit—a considerably higher resistance than that of the Richmond machine. No grade being given for these figures of Mr. Snell, they are supposed to be for working on an English tramway at level. One of the Richmond machines will easily run such a car under the same circumstances about six miles per hour.

As a matter of comparison between English and American machines, possibly the following figures will give Mr. Snell food for reflection.

One of our latest railroad machines, designed to work on a circuit varying from 400 to 500 volts, and up to a normal capacity of the former potential of 12½ horse-power, has a resistance of about 1·4 ohm on the last step. The normal magnetic circuit outside of the gap is entirely of wrought iron, and the characteristic of the machine up to its normal load is very nearly a straight line, and about equal to that of the best Edison-Hopkinson dynamo.

One of our earlier machines was a motor designed to develop 15 horse-power on a 220-volt circuit. A special committee from the Massachusetts Institute of Technology about a year ago tested one of these machines at 186 volts, a brake-load of 21 horse-power, and with about 60 per cent. current over load. Its commercial efficiency under these abnormal conditions was 78 per cent. Some of our standard machines have the following characteristics:—

Capacity. Horse-power.	Volts.	Armature Resistance.	Shunt Field Resistance.	Ratio of Resistances.
20	220	·082	150	1,829
25	220	·058	140	2,414
30	440	·228	440	1,930

The ratio of motor electromotive force to the initial when under full load is, say, for the 25 horse-power motor nearly 98 per cent., and all these machines have a commercial efficiency of over 90 per cent.

I should be glad to know of any English machines, whether of 1885 or 1888 design, which leave much to be desired in the above in the matter of regulation or efficiency. I have given these figures to show the uselessness of Mr. Snell's self-complacent disparagement of American machinery, and to emphasise the fact that any just comparison of designs should be made under like conditions, and any other comparison, whatever its motive, is not only unfair but misleading. It will give me pleasure to show, possibly at an early date, the characteristics of the Richmond machines wound for storage battery work, and also the theoretical and brake curves of our heavier railroad and standard stationary machines.—Yours, &c.,

FRANK J. SPRAGUE.

New York, October 22, 1888.

[We think it probable that Mr. Sprague would have somewhat modified the tone of his opening remarks had he been aware of the fact that in whatever way Mr. A. T. Snell's experience may compare with that of American electricians, we know of no one in this country who has a more extended and practical knowledge of electric motors. –ED. *E.*]

CABLE TESTING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reference to some remarks made by Mr. C. Bright at the recent meeting of the Society of Telegraph-Engineers, and published in *The Electrician* for November 16th, I should like to make some observations.

Mr. Bright's statement that 102·38 per cent. is at the present time "quite an ordinary conductivity for copper intended for telegraphic purposes" will come somewhat as a surprise to those engaged in the testing or manufacture of cables, as an average conductivity of 98 or 99 per cent. is generally considered an excellent result.

I quite agree with Mr. Bright that too much reliance should not be placed on his proposed method of calculating the temperature of a cable by the variation in its dielectric resistance, and of using the result as a check on the temperature coefficient of the conductor.

The said temperature coefficient might, indeed, come out somewhat higher (or lower) than that given for Dr. Matthiessen's standard; at any rate, it is not desirable that the "fresh standard" which Mr. Bright is anxious for, should have its temperature coefficient determined in this way.

The "practical examples" for calculating the effect of pressure on the dielectric resistance of a cable at depths of 2,000 and 3,000 fathoms are very curious; at first sight I thought that one or more of the "incipient faults" must have disappeared from the cables in sinking through the last 1,000 fathoms, as otherwise the increase of resistance due to pressure should come out directly proportional to the pressure.

According to the Paper of the late Sir William Siemens, referred to by Mr. Bright, it was to be expected that if the

Digitized by Google

pressure at 2,000 fathoms increased the dielectric resistance by 123 per cent., the pressure at 3,000 fathoms would increase it by 184·5 per cent. (or by one and a-half times 123); but instead of that we are told that the increase jumps from 123 per cent. for 2,000 fathoms to 889 per cent. for 3,000 fathoms.

On looking into Mr. Bright's figures more closely the explanation of this discrepancy appears to be that in the example at 2,000 fathoms the pressure correction is applied to the resistance which the cable had at 75°F., whereas in the example at 3,000 fathoms the correction is applied, but only as regards the last 1,000 fathoms, to the resistance of the cable at 36°F.

The numerical results obtained and the inferences drawn are, in consequence, a little mixed.

I think the figures should stand thus:—

For 2,000 fathoms—

Resistance of cable at 36°F. in megohms per knot	6,737
Increase of resistance due to pressure = 123 per cent....	8,287
Corrected resistance	15,024

For 3,000 fathoms—

Resistance of cable at 36°F. in meghoms per knot	6,737
Increase of resistance due to pressure = 184·5 per cent.	12,430
Corrected resistance	19,167

Yours, &c., MEGOHM.

TELEPHONE CALL-OFFICES IN LONDON.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: To satisfy "A.S.T.E. and E.," and arrive at the facts in regard to the opening of the first telephone call-offices in London, I have examined the lists of subscribers issued by the United Telephone Company, and find the following announcement in the list dated August 1, 1881:—

"CALL ROOMS AND COMMISSIONAIRES.—Telephones have been fitted up at the following call rooms, where they are available, free of charge, for the use of all subscribers or their clerks, and where the general public are requested to inspect them and test the working of the system:—224, the United Telephone Company, 36, Coleman-street; 3553, office of the Corps of Commissionaires, 419A, Strand; 2561, 2562, Lonsdale Chambers, 27, Chancery-lane; 3044, 3045, Metropolitan District Railway Station, Westminster Bridge. Commissionaires are also stationed at these call rooms, and the services of a member of the corps can immediately be obtained on telephoning to any of the above numbers. Employers wishing to communicate with the adjutant of the corps on any matter of business can now do so from almost any part of the metropolis."

These rooms were used by the general public as well as by subscribers.

By August, 1881, four call rooms had therefore been opened in London; but, as a matter of fact, at least one, that at Coleman-street, had been in use for some considerable time before, and, for the special benefit of the legal fraternity, a call room was opened in the Temple as early as April, 1880.

In view of these facts, I cannot see how I am "basing on information that *must* be inaccurate;" or how, to quote your correspondent again, "it is matter of common knowledge in telephone circles that there was no call office in London prior to 1883." It appears to me that the common knowledge in telephone circles on the matter is proved to be common ignorance, and of a piece with other delusions which appear to be prevalent in regard to the United Telephone Company and its working.

"A.S.T.E. and E." states that in 1880 there was a call office in Edinburgh. I accept his statement unreservedly, but I may remark that it could not have been established by the existing telephone company—the National—for the simple reason that the National Telephone Company did not come into existence until March 10, 1881, *vide* the *Monthly Investment List* (Sept. 1888 of "Mr. Faithful Begg.")

In conclusion, I trust these remarks will definitely satisfy "A.S.T.E and E." I have no wish to discuss the matter further.—Yours, &c. J. MUNRO.

November 19, 1888.

ON THE ACTION OF LIGHT ON STATICAL CHARGES.*

BY F. NARR.

The author proposes to measure the rate of leakage of one plate of a condenser when charged with positive or negative electricity, and to observe if there is any difference in the rate according as the plates are illuminated or in the dark. The illumination was by means of a magnesium lamp, and the smoke caused by it was removed from the condenser as far as possible, so that the magnesia dust should not affect the rate of leakage. The room at his disposal for the experiments did not allow of an electric lamp being used.

The condenser had two parallel circular plates, separated by an air space of 2 centimetres. The plates had their planes vertical, and one (which he calls the "inner" plate) was usually charged and connected to the electrometer, the other ("outer") insulated or put to earth. The connections could be made almost instantaneously by suitable mercury cups.

(1) The light was placed in the plane midway between the two plates, and screened off. The outer plate being permanently insulated, the inner one was charged by connecting to the previously charged electrometer, and two minutes after this connection was made the charge was measured. It was again measured at the end of another two and four minutes respectively. The experiment was performed again with the light screen removed for half a minute between the first and second readings of the charge. No difference was found in the rate of leakage between the dark and illuminated condition of the plates either for a + or − charge of the inner plate.

(2) The outer plate was put to earth just before the first reading of the charge. The rest of the experiments as before. Again no effect was observed due to the light.

(3) The light as before, but left shining on the plate for two minutes, outer plate put to earth before reading charge first time. Still no effect due to light could be observed.

(4) The light in same position as before. The operations as follow:—Charge inner plate, outer one insulated. Connect electrometer to inner plate.

After 2min. read charge.
,, 3½min. begin illumination.
,, 4min. put outer plate to earth and read charge.
,, 4½min. cut off illumination.
,, 6 and 8min. read charge.

There was no effect seen in this case, in which the outer plate is put to earth *during* the illumination. The remaining experiments were made on the inner plate of the condenser alone, which was then freely charged with electricity, the outer plate being removed. The light was placed 19 centimetres from the centre of the plate and on its axis. The plate was charged and allowed to stand two minutes, charge read and illumination commenced, at end of 2½min. illumination stopped, charges read at end of 4, 6, and 8min. The experiment was repeated in the dark, and the result shows that the illumination produces an apparent discharge of the plate, which is of greater amount in a positively than in a negatively charged plate.

An experiment repeated with light 22 and 25 centimetres away from plate showed that the apparent discharge falls off rapidly with the increased distance of the light, but is always less for a negative than a positive charge.

The next experiments were made to ascertain the effect of long and short duration of illumination. The plate being 19 centimetres from the light the losses in 4min. were as follows:—

Duration of illumination.	Loss of charge in 4min. +	−
5 sec.	0·0367	0·0294
30sec.	0·0887	0·0661
60sec.	0·3948	0·0839

The author concludes by pointing out that the effects cannot be considered as due to dust from the lamp, because the rate of discharge with the plate in the dark was far less than when illuminated, even though the air was dusty with the magnesia from the lamp in each case.

COMPANIES' MEETINGS.

Eastern Telegraph Company (Limited).

An extraordinary general meeting of the members of this Company was held at Winchester House, 50, Old Broad-street, yesterday (Thursday), to consider resolutions increasing the Ordinary share capital of the Company from £3,800,000, to £4,000,000, by the creation and issue of 20.000 new shares of £10 each. Sir John Pender occupied the chair.

The SECRETARY (Mr. Geo. Draper) having read the notice convening the meeting,

The SOLICITOR (Mr. Burt), at the request of the Chairman, read the following resolution which it was intended to submit to the meeting:

"*That the Ordinary share capital of the Company be increased from £3,800,000 to £4,000,000 by the creation and issue of 20,000 new shares of £10 each.*

"*That such new shares shall rank for dividend equally with the existing Ordinary shares as from 30th September, 1888.*

"*That such new shares be in the first instance offered at the price of £14 per share (£2 per share premium) to the members of the Company registered on the 22nd November, 1888, as holding 10 or more Ordinary shares—holders of from 10 to 20 Ordinary shares to be entitled to one new share, and holders of more than 20 Ordinary shares to be entitled to one new share for every complete 20 Ordinary shares held.*

"*That all new shares not accepted by the members entitled thereto and £2 per share duly paid thereon, be allotted and disposed of by the Board of Directors as they think expedient.*

"*That the amount of the new shares and premium be payable as follows:—£2 per share on or before the 2nd December, 1888; £5 per share on or before the 15th December, 1888; £5 per share on or before the 15th January, 1889.*

"*That upon completion of the payments the premium of £2 per share be carried to the general reserve fund, and the share certificates issued.*

"*That the Directors may require interest at £10 per cent. per annum on any instalment (after the first £2 per share) in arrear.*

"*That, subject as aforesaid, the details, terms and conditions of the issue be such as shall be determined by the Board of Directors.*"

The CHAIRMAN: You have heard the resolution read, but before I ask you to approve of it I think it will be interesting to you, and only right for you to know, the reason why we ask for this increase of capital. The last time that we called upon the shareholders to sanction an extension of capital was in 1872. At that time there was an amalgamation of different companies. There were four or five in number, which were put together under the title of the Eastern Telegraph Company. As an instance of the growth of this Company, the following figures may prove interesting:—On the amalgamation in 1872 the Eastern Company owned 8,862 miles of cables, and owned and rented about 1,200 miles of land lines. They had 24 stations and two cable repairing ships. The capital was £3,397.000. The gross revenue was about £376,922 per annum. That was in 1872. At March last the total capital was £5,900.000, and the gross annual revenue £650,971. The cable mileage was 22,405 miles, and with the Eastern and South African Company's existing cables and the extension to Loando the total will be 29,108 miles. The increase in the capital issued since the amalgamation in 1872 is therefore £2,503,000, and in addition over £700.000 has been applied from the reserve fund, and a new ship costing over £45,000 has been paid for out of the ships' fund. The additional capital was raised as follows:—£403,000 by Ordinary shares, £700.000 by Six per Cent. Preference shares, £232,000 by Six per Cent. Debentures, £650.000 by Five per Cent. Debentures, and £518,000 by Four per Cent. Stock. £682.000 has also been issued at 4 per cent. to replace the Six per Cent. and Five per Cent. Debentures for a like amount, so that out of the 2½ millions of new capital raised since the amalgamation £1.200.000 bears only 4 per cent. interest, effecting a saving to the Company of £9.140 per annum in interest. The remaining £200.000 Five per Cent. Debentures will be replaced in 1899 by the issue of a like amount of Four per Cent. stock. With the new capital raised and the contributions from reserve and revenue the following work has been done:—Duplicating (839 miles) the cable between England and Lisbon, and extensions in Levant; completing the Levant extensions; the Sardinian cable, for which we receive a subsidy of £4,400 per annum; duplicating Suez-Aden and Aden-Bombay cables; Marseilles-Bona and Bona-Malta cables; purchase of Black Sea Company; connecting Cyprus with Alexandria; purchase of South African shares; triplicating the Red Sea, Malta, Tripoli, and Greek cables (and we receive a subsidy from Greece of £6.500 per annum); purchase of Mediterranean Extension Company; purchase of shares in the African Direct Company; and duplicating the Portheurnow and Malta cable and extension to Zante. That shows what we have done with the money, and I will now show you the increase that has, so far, taken place in the number of our stations, as compared with the number that I stated first. We have got in England 7, Scotland 1, France 3, Spain 3, Portugal 5, Egypt 5, Greece 10, Turkey 13, India 1, Austria 2, Cyprus 7, Russia 1, Morocco 1, Barbary 1, Gibraltar 1, Malta 1, Perim 1, and Aden 1. That makes a total of 64, so that we have increased the number of our stations to that extent from 24. We have at the same time added three ships to our fleet. That shows you, gentlemen, the marvellous growth in the last sixteen years in our system, and that growth has been largely facilitated by our keeping ahead of the requirements of the public. Our asking you to-day to come and sanction this increased capital is to enable us still further to secure the interests of this Company and also to secure permanency to the telegraphing public. The object of our asking you to raise this £200.000 is to duplicate the South African system which we took in hand in 1879. At that time the whole question was before the shareholders. When we first made our proposal in connection with the South African Company there were a great many people who did not believe that that system would pay. Your Board held a very different opinion, and we went at it with a will, determined, as far as we could, to carry it through. We went to considerable expense in the original construction of the Company. We took a large interest in it, and taking that interest in it we believed, if it were successful, that eventually it would be an enormous benefit to this Company. At the time, however, there was so much said as to the propriety of the Eastern Company taking the whole of the responsibility, that other companies shared the risk with us, and at that time, when it was brought before the Board in July, 1879, the Board considered it inexpedient that the Eastern Company should take the entire responsibility of the undertaking. In the Directors' report to the general meeting of the 14th July, 1879, we said:—"As the Board considers it inexpedient that the Eastern Company should take the entire responsibility of this undertaking, it is intended to form a separate Company, to be called the Eastern and South African Telegraph Company, with a share capital of £400.000, and Mortgage Debentures for £600.000; but as the entire management and working of the cables will be in the hands of the Eastern Company, and the traffic will pass over their wires from Aden, the new lines will practically be an important addition to this Company's system, and in consideration of the advantages which will be derived therefrom it has been agreed, subject to the approval of the shareholders, that £200.000 of the share capital, and if necessary a portion of the debentures, shall be subscribed by this Company, and a rebate be given upon the traffic obtained by the Company from the new lines. As the debentures are to be paid off by means of an accumulative sinking fund, the Eastern Company will thus obtain half the reversionary property in the new lines, whilst the Company's holding in the share capital will give them an effective control." You will see from these remarks that we exercised caution and prudence in going into this South African Company. During that time the South African Company has grown to very large proportions. What with the diamond and gold speculations at Zanzibar the traffic has been good, so much so that it became absolutely necessary that that system should be duplicated, and therefore, instead of duplicating the system by which we approach the Cape at the present time, namely, by the East Coast, the Board resolved to carry a line by the West Coast. The South African Company are to carry out that line: but the South African Company being practically the property of the Eastern Company, the benefits derived will of course accrue to the Eastern Company. Before, however, we decided to take this step—a step which is desirable for the security of the traffic, and to give something like permanency to telegraphic connections which exist at the present time, and which are so important to the public—before we took that step different companies had been formed in connection with the West Coast of Africa. One of those companies is the African Direct Company, of which we have practically the management—that is, so far as all practical purposes are concerned—in our own hands. There is another company, called the West African Company, and we have practically secured that, its management being also in our own hands. Therefore, by laying a new line from the Cape to connect with this existing system, we get an alternative line from London direct to the Cape, so that we cut both ways. We encircle Africa, and at the present time, when all the different Governments of Europe are looking at this dark country with the view of developing it, as it has always been our policy to be ahead of requirements, the telegraph will by our proposal be there when they want it to assist in the development, and there is no system that tends so much to promote and develop commerce for the interests of a people as the telegraph. I think I have now shown you that we are in a position of controlling Africa by our system. The present scheme is to be carried out on the principle of shares and debentures. We ask you now to increase the capital of the Eastern Company by £200.000. That money is to be expended to purchase shares which the South African Company are going to issue, and we become practically proprietors of the South African system. £300,000 of debentures which are also required—because the whole system will require half a million of money to complete it—we shall issue to our own shareholders *pro rata*. Those debentures are a good property. They are in demand, and probably stand at as high a premium as any security of an equal kind stands at present in the market. Therefore, what we are asking you to do is simply to give us the power to increase the value of your own property. When these concessions expire, we shall find ourselves at the end of ten years, and again at the end of twenty years, in possession of this vast system to South Africa, profitable, and I believe increasingly so, and we shall find ourselves in possession of it at a comparatively nominal value. We shall hold the shares, but all the debentures by that time will have been paid off, so that we hold all that extended system simply for the share capital which we shall hold at that time. I think I have now given you a fair statement of the facts, and I think you will agree with me that the policy we are pursuing of keeping the South African Company entirely in our own hands is a good one. The having the management entirely in our own hands of the existing system to the West Coast gives a security to the shareholders of a permanency to the telegraphic system, such as it would have been impossible to get had the thing been in different hands. As you know, a concentrated management in telegraphs is an absolute necessity, in order that the advantages of speed may be fully realised. If telegraphic communications were to pass through different hands, and to be dealt with by different companies, the delays would be such as to make telegraphing almost impossible. As it is, by our system, an interruption occurred the other day on one of the sections, which was then in other hands, and the telegrams were occupying four days as against two hours when our system was in complete working order. You can see the advantages, therefore, which

Digitized by Google

are obtained by this concentration. On these grounds I ask you to-day to approve of the resolution which has just been read to you, and which I now move, holding that it is a safe and sound movement on the part of the Eastern Company. If anyone has any question to ask before I put the resolution I shall be happy to reply to him.

Lord TWEEDDALE seconded the resolution.

In reply to a few questions that were asked,

The CHAIRMAN said that the Directors had worked out the figures, and found that after giving every shareholder his proportion of shares as set out in the resolution there would be 1,900 shares left, and as they had 1,700 shareholders holding under ten shares each, they proposed, in order to encourage the shareholders, which they were desirous of doing whenever they could, to make an offer to those who held less than ten shares, or even one share. The debentures they proposed to offer to the shareholders of the South African in common—£300,000 debentures *pro rata* if they chose to take them at 4 per cent. and at par, although they were at a good premium at the present time. A holder up to twenty shares would, according to the programme, receive one share—one share for every twenty shares. He then put the motion, which was carried unanimously.

A vote of thanks to Sir John Pender for presiding, and to the Directors for the able way in which they managed the affairs of the Company, was then proposed, seconded, and carried unanimously.

The CHAIRMAN, in reply stated that nothing was so satisfactory to him and the Directors as to have the confidence and approval of the shareholders. The Company had grown during the last sixteen years by leaps and bounds, maintaining a fair dividend during that period, and conferring enormous benefit on the public generally. He saw the Company growing stronger and stronger every day.

The proceedings then terminated.

South of England Telephone Company (Limited).

An extraordinary general meeting of the South of England Telephone Company was held at 50, Old Broad street, yesterday (Thursday), Mr. D. O. Bateson presiding, for the purpose of considering and, if approved, of passing the following resolutions :—

(a) *That the following words be added at the end of Article 11 of the Articles of Association of the Company :—"Provided also that no call shall exceed one-fourth of the nominal amount of a share, or be made payable within two months after the last preceding call was payable."*

(b) *That Article 15 be repealed, and the following Article be substituted in lieu thereof :—"15. The transfer of any share in the Company shall be by deed or deeds on the usual common form of transfer. There shall be paid to the Company in respect of the registration of any transfer or transmission such fee not exceeding 2s. 6d. as the Directors deem fit."*

(c) *That the words "not fully paid up" be inserted after the word "shares" in Article 17.*

(d) *That the words "not fully paid up" be inserted after the words "the Company shall have a first and paramount lien on all shares" in Article 21.*

(e) *That the word "tenth" be substituted for "fifth" in Article 40.*

(f) *That all the words after "claimed" be omitted from Article 98.*

Mr. FRED. L. ROBINSON (the secretary) read the notice calling the meeting and the above resolutions.

The following is a circular issued by the Directors :—

"In accordance with the suggestions made at the last annual meeting, and the wish since expressed by influential shareholders, the Directors have taken steps to obtain from the committee of the Stock Exchange a quotation for the shares of the Company. There are a few minor points in the Articles of Association which do not accord with the rules of the Stock Exchange, and consequently require to be altered; this can only be done at an extraordinary general meeeting of the Company.

"During the past half-year trunk lines have been completed between Canterbury and Dover, Lewes and Eastbourne, Wellingborough and Kettering, and an exchange has been opened at Kettering.

"At the 31st October last 1,629 exchange lines and 437 private lines were completed, and 64 exchange lines and 13 private lines were in course of construction. The progress made as shown by this statement is considered satisfactory by the Directors.

"The dividend on the Six per Cent. Preference Shares up to the 31st ultimo has been paid.

"Comparative Statement of Exchange and Private Line Business.

	Exchange.	Private.
April 30th, 1886	687	248
April 30th, 1887	1,130	348
October 31st, 1887	1,316	373
April 30th, 1888	1,521	386
October 31st, 1888	1,693	450"

The CHAIRMAN said that the shareholders were all well aware of the object for which they had been called together that day, it having been fully stated in the circular sent out, and he did not therefore wish to detain them with any lengthened observations, but would just like to know whether they would have the alterations submitted each as individual resolutions, or would take them *en bloc* in one resolution (a Voice: "Take them *en bloc*"). They were of a very trivial nature, and he thought they had already acted up to them. The first alteration was in Article No. 11, viz., "Provided also that no calls shall exceed one-fourth of the nominal amount of a share." Well, they had never made a larger call, he believed, than one-tenth.

The SECRETARY said 10s.

The CHAIRMAN (continuing) said further that no call should be made payable less than two months after the last preceding call was payable. Well, the calls had been made at much longer intervals than that; the first was made after an interval of 15, and the second after an interval of 13 months, and there was, therefore, no likelihood of any difficulty arising in the future in the matter of calls. With respect to the next alteration, Article 15 was repealed altogether, and a fresh article substituted in its place. He might state that they had always used the common form of transfer, although not previously compelled to do so. The new article, however, compelled its use, repealing the power previously possessed to use other forms. They had always charged 2s. 6d. for transfers, so that part of the article remained precisely the same. The next alteration had reference to any lien the Company might have upon shares, and provided that the lien should only apply to such shares as were not fully paid up. Then in Article 40, which provided that the Directors should whenever they thought fit on a requisition in writing, signed by at least one-fifth of the capital, call a special meeting, an alteration had been made reducing the number that could call a meeting to one-tenth, so that in the future a smaller number of dissentients could, if they wished, have a meeting. He moved formally that all these alterations should be passed.

Mr. ALEXANDER MACGREGOR seconded the motion.

Mr. BEVIS: Before you put it, Mr. Chairman, do I understand that if the shares had been fully paid-up there would have been no necessity for these alterations?

The CHAIRMAN: That would have done away with them all.

A SHAREHOLDER asked whether there was any intention at present of calling up the balance of the money and making the shares fully paid-up?

The CHAIRMAN said they would call it up as fast as they wanted it, but they had no wish to pay 6 per cent. on money they did not require.

Mr. BEVIS: I wish you had sufficient business to make you do it (hear, hear).

The resolution was then put and carried.

The CHAIRMAN: We shall be obliged, in accordance, with the Statute, to call another meeting within a short time to confirm this resolution. It will be held this day three weeks at the same time and same place. That, gentlemen, is the whole of the business. We are very much obliged to you for your attendance, and we are glad to have such a unanimous meeting.

A vote of thanks to the chairman terminated the proceedings.

PACIFIC CABLE CONFERENCE.

A conference of the public interested in the telegraphic system between Great Britain and her Australasian dependencies was held yesterday (Thursday) in the Cannon-street Hotel, to consider the laying of a Pacific cable from Canada to Australia.

The Right Hon. the EARL of WINCHILSEA occupied the chair, and in opening the proceedings said he felt it a very high honour to be called upon to preside over such a conference as that, and he was very glad to see such a large and representative gathering assembled on the occasion, as showing how great an interest was taken in the subject by busy City men. He would not take up very much of the time of the meeting as Chairman, because what they desired was to obtain an independent expression of opinion from them as commercial men whether or not the time had not arrived—whether, indeed, it was not high time—that something was done to improve the telegraphic communication between this country and the Colonies of Australasia. But one or two words he would like to say as to one, if not more, of the many aspects of that great Imperial question. First of all let him say that they were assembled there simply as men of business to set forward their own interests as traders. They were not there to attack other people; they were not there even to fail to realise or to recognise the great debt which they owed to those who had been the forerunners in the matter of telegraphic communication. They were met simply to ask themselves, and to answer the question, whether the means of communication which at present existed were sufficient, whether they were safe, and whether they were as cheap as they ought to be? With regard to the present means of communication, he thought they could hardly be called cheap; he should say almost that the word prohibitive would be more applicable to the tariff which at present obtained between this country and Australasia. The rate of 9s. 8d. must lead, if not to a prohibitive, to a very restricted intercourse indeed. It led, as he knew perfectly well—having had relations out in the Colonies himself—to that sort of intercourse which made people compress their messages into such a small space that very often when they arrived at the other side of the world they were totally unintelligible. As regarded the second essential, its continuity, there again he must point out that no less, he thought, than three times during the last four months had telegraphic communication between this country and Australasia been entirely interrupted. Then again, with regard to its safety, they had, of course, to consider that there were only two states in which the world could be—one was peace and the other was war. With regard to the safety of their existing lines of communication in time of war, it was not too much to say that they would be absolutely defenceless, and without the means of defending them if they were involved in a great European war. The fact that the present lines of communication passed through Suez rendered them of course exceedingly liable to any interruption from that cause. Egypt had been the battle-field of the world in other generations, and might be in their own, and nothing was more certain, he thought, than that if they were

Digitized by Google

involved with any great European Power in a war in Egypt that means would be found to cut entirely the communication, which it would be impossible for them to prevent, and they would possibly be placed in the position of being for six weeks cut off entirely from Australia. That was a contingency which, from an Imperial point of view, they could not possibly contemplate without the greatest apprehension. In so far as those three requisites—cheapness, continuity, and safety—were concerned, he thought the remarks he had made with regard to their present system would probably meet with the approval of the Conference. With respect to the proposal made to them it was simply this, that a line of cable should be laid from Vancouver to Australia, touching at Hawaii, Fanning Island, Samoa, and Fiji. Of course, the existing lines of communication between this country and Vancouver were very strong and dependable. It was fair to say that from this country there were so many lines across the Atlantic at the present moment that, having in view the interests that the United States must have, as well as themselves, in maintaining that communication, it was all but impossible that it should ever be destroyed between the two countries. Then we had entirely on British soil the Transcontinental line of wire through Canada, which landed them at Vancouver, and thence across the Pacific at unknown depths: but with regard to the subject of the depth at which they could lay a cable across the Pacific he would content himself by saying that the question had been referred to experts, and their consensus of opinion was that it was a perfectly practicable route, and he would remind them that there was a cable in existence to Pernambuco which was only 200 miles less in point of length. The experience of deep-sea cables was this, that they were very much less liable than were cables in shallow seas both to the attacks of insects on the one hand, which often destroyed cables, and to the action of the currents on the other, which caused considerable attrition at the bottom of the sea. The bottom of the Pacific was, generally speaking, except at the equator, where the cable could easily be protected, composed of a kind of soft mud which was very favourable to the laying of a cable. At the bottom of the sea at great depths the water was colder than in shallow waters, which was also favourable to the life of a cable, and, as he had said, there were no currents there, while the existence of animal life at the pressure of great depths was improbable, if not altogether impossible. Another point in favour of a deep sea cable was of course its great safety in time of war. It would be extremely difficult, if not impossible, to destroy a cable at the depth at which they proposed to lay it, and therein would lie a very great Imperial safeguard. There had been a printed letter circulated extensively that morning by those who represented the Eastern and Eastern Extension Companies, and he thought it would only be right that some answer should be made to that letter on behalf of the Company which had brought them together that day. He would not further refer to it now, but he would before the proceedings closed ask his brother, Mr. Harrold Finch Hatton, to go through that letter *seriatim*, and give such a reply to it as his experience would enable him to do. It remained for him now to point out to them that a very great advantage would be gained by a reduction of the tariff from 9*s*. 8*d*. to 4*s*., as they would easily comprehend. It would revolutionise entirely the business arrangements and the way in which they would be conducted between England and the Colonies, very much to the advantage of business. It would probably lead to a very large development of the trade, which was quite ready to spring up between the western shores of the Pacific and their colonies in Australasia which would be a British trade. Therefore, it was one in which they would take an interest, and from which they would look for a great increase of traffic on their line, which would make it remunerative. There was one point which had been misapprehended with regard to the guarantee that had been asked for from the Governments. That guarantee was not in the nature of a subsidy, but merely a guarantee that the Governments would, in a proportion arranged between themselves, guarantee to use the cable to the extent of £75,000—that was to say, they might have a *quid pro quo* by using the line to that extent, which they would apprehend was a very different kind of guarantee from that which agreed to pay so much money without getting the benefits from it which they had a right to expect. With regard to the Imperial nature of the problem, they all knew how trade followed the flag. Figures told them that their trade with Australia was about £8 per head, while that with the United States and other English-speaking people was only 8*s*. a head. Therefore, everyone would agree with him and say that they ought to encourage that trade. That would be facilitated by a line of communication laid almost solely—he ought to except Hawaii, which was under the joint protection of themselves and the United States—within the control and the limits of the British Empire. In the event of war it would be possible to land a great number of troops at Vancouver, and to draw them from thence to India and Australia, and in a shorter time than could possibly be done supposing their communications through the Suez Canal were interrupted, than had they to send them round the Cape. That was a great factor in the Imperial problem, to which he drew their attention. The whole scheme involved this. It involved two if not more lines of subsidised mail steamers, which would be armed cruisers carrying the mails in the Pacific, and a telegraph line to correspond with their line, and in that way he thought they might say that England would sufficiently protect her interests in the Pacific. There was great competition going on at the present moment, he believed, between Canada and the United States as between two points, San Francisco and Vancouver, to determine whether the Pacific trade should concentrate upon San Francisco and be carried by the United States lines across towards Europe, or whether it should concentrate itself at the British port of Vancouver and be carried by the Canadian Pacific to this country. Now they would follow him when he said that Canada, having made, after great exertions, the great Imperial route of the Canadian Pacific Railway, which had cost 57 millions of money, in order to make one of the great piers of the arch of communication which ought to join England and Australia, deserved well of the mother country. She was deeply interested in this scheme, and he was very glad to know that he would have the pleasure of calling on Sir Donald Smith to move a resolution in favour of it. The Australian Colonies had not been behindhand either in the interest which they manifested in the scheme. It was a most significant fact that this was probably only the one great public question on which Victoria and New South Wales were really agreed, and therefore he thought it was a good omen for the success of the undertaking that the Australian Colonies had taken it up as warmly as they had done, and that Canada had shown so great an interest in it. His hearers, who lived in the great centre of British trade, ought not to be behindhand in recognising from their point of view its immense importance, as had been freely done in Canada and Australasia. If the project were carried out it would be for them to say what would be its importance from a commercial point of view. They should undoubtedly then be put in possession of a means which would open up the Pacific as it had never been opened to British trade and British influence. They should divert, he believed, the main volume of traffic to the British instead of to the American centre, and they should also be in possession of a line of telegraphic communication which would be at once a second string to their bow, and also a cheap, safe, and continuous line of communication between England and her great dependencies. He felt that he had detained them at greater length on the subject than he ought to have done; but the fact that they had gone there in such large numbers proved to him the deep interest which they took in it. He had great pleasure in calling on Sir Donald Smith to propose the first resolution.

Sir DONALD SMITH moved the following resolution:—

"*That in view of the unsatisfactory state of the existing telegraphic communication between Great Britain and Australasia, this meeting most strongly approves of the proposal of the Pacific Telegraph Company (Limited), to lay a cable across the Pacific Ocean from Vancouver Island to Australia, touching at Hawaii, Fanning Island, Samoa, Fiji, and New Zealand, and to reduce the tariff from Great Britain to Australasia to 4s. per word, and that this meeting, believing that the laying of such a cable would be of great benefit to commerce in time of peace, and a safeguard to Imperial interests in time of war, trusts that Her Majesty's Government will do all in their power to facilitate the laying of such a cable, especially by obtaining the necessary soundings with as little delay as possible.*"

He said it was gratifying for him to be present to advocate, as far as he possibly could, an enterprise which had been so ably placed before them by the noble Chairman, and which he believed to be worthy of every support that could possibly be given to it by the commercial community of London, by the people of England, and by the Colonies, as he believed it to be in the true interests of the Empire at large. He believed the scheme would be of considerable advantage to Great Britain as well as to the greater Britain.

Mr. DOXATT (of the firm of Messrs. Dalgety and Co.) seconded the motion, and spoke of the inconvenience to which commercial men had recently been put owing to the recent interruptions to the existing Australian cables.

Mr. BLACKWOOD, as an Australian born, advocated the proposal as of considerable importance in connection with Imperial federation.

Mr. J. McEWIN trusted that those connected with the new scheme would not trust to the Governments for help. He considered it was a most important scheme, going as it would across British territory entirely, and, in his opinion, there was no physical difficulty at all in connection with the construction of the cable.

Mr. WESTGARTH said he had just returned from Australia, and not having been there for many years he had been struck with the enormous progress which had been made in the Colonies.

The CHAIRMAN put the motion, which was carried unanimously.

Mr. HARROLD FINCH-HATTON said that the presence there of so many business men in the busiest part of the day showed the great interest taken in the proposal. He then referred to a circular which had been issued by the Eastern Telegraph Company, and replied at length to the statements contained therein. They had asked for Government support to the scheme, but were met by the statement that it would not be fair to support a scheme which came into competition with the existing cable system. There might be something in the objection if the proposed cable were to be laid exactly over the ground occupied at present by the Eastern Extension Company, but such was not by any means the case. He submitted that they were deserving of every support from the Governments for several reasons, and the whole question was purely one of national existence. He maintained that the existing system could not in fairness be described as under British control, passing as it did through different foreign countries, and said that the proposal of the Pacific Cable Company in connection with the depth at which they proposed to lay their line was one of the greatest possible safeguards in connection with the life of the cable. He then spoke of the interruptions to the present cable and the inconvenience and dangers thus incurred. It was perfectly evident that some sort of sacrifice must be made by the various parties interested in the proposal in order to secure for themselves mutual advantages, which they could not expect for nothing, and he maintained that if the British Empire, by an outlay of £75,000 a year for 25 years, a large portion of which would return into the public exchequer in the form of free Government messages, got the advantages he pointed out it would have received uncommonly good value for its money. Whether or not, however, a guarantee were given, he was convinced that the projected cable would be laid, so strongly did the Colonies support it.

On the motion of Mr. BLACKWOOD, seconded by Sir DONALD SMITH, a vote of thanks to the Chairman was passed.

The CHAIRMAN, in reply, expressed a hope that their efforts that day would be the means of forging one other link in the chain which bound the mother country and the Colonies together.

The proceedings then terminated.

Digitized by Google

THE PACIFIC TELEGRAPH SCHEME.

The following letter has been addressed to the editors of the leading daily papers:—

"Sir: The circular sent out by the Pacific Telegraph Company, convening a meeting, to be held on the 22nd instant at the Cannon-street Hotel, to consider and pass a resolution in favour of their proposal for laying a cable from Canada to Australia, contains the following statement, namely, that 'the extremely unsatisfactory state of the existing cable communication between England and Australasia is injurious to trade, and would be a source of great danger to imperial interests in time of war.'

"In thus endeavouring to disparage the existing communication, the Pacific Telegraph Company doubtless hope to further the objects they have in view, but as the statement is most exaggerated and misleading, my directors trust you will find space in your valuable paper for the following remarks, in order that any false impressions created in the minds of those attending the meeting may be removed, and that the telegraphing public may have both sides of the question before them.

"The existing communication with Australia was established by the Eastern Extension Company in 1871, without subsidy or assistance of any kind from the Colonies or the Imperial Government, and subsequently, when the importance of telegraphy became more fully realised, and a duplicated system a public necessity—not because a single line was unequal to the transmission of the traffic, but in order to provide against the interruptions inseparable from a single line of cables—the colonies of Victoria, New South Wales, South Australia and Western Australia agreed to give the company a subsidy of £32,400 per annum for 20 years, to enable it to duplicate the cables between India and Port Darwin. Since then the telegraphic communication has been very seldom interrupted, a result due to the duplication, and in some sections triplication, of the cables, and to the fact that they are laid for the most part in shallow water, and are consequently repairable at almost all seasons of the year.

"Unfortunately, during the past few months the communication has been thrice interrupted through exceptional circumstances, and the public, not adequately appreciating the enormous difficulties and expense inseparable from the efficient maintenance of submarine telegraphy, have made little or no allowance for the same. On the first occasion both the Java-Australian cables were suddenly and simultaneously interrupted in deep water through volcanic disturbances, and the two subsequent breakages were in connection with the renewals of portions of the cables where they were found to be on bad ground and in dangerous proximity, owing to the strong currents off Java having drifted them together.

"The total interruptions, however, since the communication was duplicated in 1880, including those above mentioned, have aggregated only forty-one days, averaging less than five days per annum, a result that will bear favourable comparison with the working of any other submarine system in the world.

"In order, however, to further strengthen the system, the company are about to lay a third cable from Java to Australia, which, by working with the Western Australian land lines, will give the Colonies the advantage of an alternative land connection *vid* Perth and Eucla to the existing overland line between Port Darwin and Adelaide. Consequently the Colonies will be provided with a complete and efficient telegraphic service by the existing system, not only equal to the transmission of a much larger traffic than it now carries, but enjoying the immense advantage of being under English control and worked by English operators throughout its whole length.

"My directors would therefore submit that the existing company, as the pioneer of telegraphic communication with Australasia, is entitled to consideration at the hands of the Colonies.

"With regard to the reflections made by the Pacific promoters as to the insecurity of the existing communication in time of war, I am directed to point out that while the route between Australia and Java and Europe is incomparably the most secure and easily protected in time of peace, it would be the most surely and easily safeguarded in time of war, inasmuch as it is one of the sea routes most frequented by the mercantile marine, and would therefore be the special object of the vigilance and care of the Royal Navy.

"On the other hand, it would be impossible for the British Government, however anxious to do so, to provide adequate protection in the case of cables laid across the Pacific, far away from the routes used by commercial ships, and at immense distances from coaling stations, and, moreover, a single line of cables, consisting of long stretches across such enormous depths as those recently reported to have been found by Her Majesty's ship "Egeria" off Fiji, namely, 4,295 fm. and 4,430 fm. (five miles deep), and terminating on coral reefs, would inevitably be exposed to frequent interruption, which would render its maintenance most costly and difficult. It should also be borne in mind that the Canadian Pacific land line, passing as it does through exposed and stormy regions, would also at certain seasons of the year be very difficult to maintain.

"The question, however, is, are the public prepared to find the necessary money for a Pacific line? If so, they must make up their minds to an expenditure of nearly four millions sterling for a duplicated service. This large expenditure, however, is in no way justified by the existing traffic, which only gives a moderate return upon the capital already invested, and, consequently, the additional outlay would prove altogether unremunerative.

"The proposal made by the Pacific Telegraph Company that Government traffic should be guaranteed to the amount of £75,000 per annum for twenty-five years is not so favourable to the Colonies as it would at first sight appear, as the whole of the traffic at present exchanged by the Imperial and Australasian Governments represents less than £16,000 per annum, and consequently the Governments would have to extend their expenditure by about £60,000 per annum to make up the amount of guarantee.

"If, however, the Colonies are in earnest in their desire to have cheap tariffs, the object can be easily attained by adopting the guarantee proposal submitted by the Eastern Extension Company to the Imperial and Australasian Governments last year, by which the Colonies might make the tariff any figure they please, provided the Eastern Extension and its associated companies were guaranteed three-fourths of their present moderate earnings from the Australasian traffic, the companies accepting the remaining one-fourth of the guarantee risk. This would give the Colonial Governments full control over the tariffs, and, in our opinion, enable them to establish a cheaper rate on more favourable conditions than could be obtained in any other way.—I am, sir, yours, &c.,

"F. E. Hesse, Secretary,
"The Eastern Extension, Australasian and China Telegraph Company (Limited).
"Winchester House, 50, Old Broad-street, London, November 21."

PATENT RECORD.

APPLICATIONS FOR PATENTS.

Note.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

15,801. A. B. Blackburn. London. An improved joint for electric light fittings. November 2, 1888.

15,865. C. J. Munier. London. Improvements in multiple printing telegraph apparatus. November 2, 1888.

15,868. A. Winkler, A. Kuhnt and R. Deissler. Berlin. A process of reduction of aluminium by electrolysis. November 2, 1888.

15,869. C. B. Harness. London. Improvements in electro-magnetic induction apparatus. November 2, 1888.

15,877. E. Rousseau. Leyton. Pocket or portable secondary batteries or accumulators. November 3, 1888.

15,910. L. Kayser. London. Improvements in galvanic batteries. [Date applied for under Section 103 of the Patents, &c., Act, 1883, April 13, 1888.] November 3, 1888.

15,915. F. V. Anderson. London. Improvements in electric arc lamps. November 3, 1888.

15,921. A. Siemens. London. An improvement in electric railway signals. November 3, 1888.

15,928. E. Duvalle and A. Dousson. London. Improvements in electrical motive power engines. November 3, 1888.

15,935. D. Latchinoff. London. Improvements in the production of oxygen and hydrogen in large quantities by means of the electrolysis of water, applicable for ballooning and other uses. November 3, 1888.

15,947. C. B. Burdon. Liverpool. Improvements in systems of electric traction for railways and tramways. November 5, 1888.

15,949. T. Pease and C. B. Burdon. Liverpool. Improved methods of applying electricity to a general system of traction. November 5, 1888.

15,961. T. Field, Jun. London. An improved electrical fabric for medical purposes. November 5, 1888.

15,989. B. J. X. Gosselin. London. Improvements in dynamo-electric machines and electro-motors. November 5, 1888.

16,001. J. Gardner. Preston. Repeating railway signals on a locomotive engine by the aid of electricity. November 6, 1888.

16,005. A. G. Burrell. Sheffield. Utilising existing telephone line wires for clock synchronising or controlling purposes. November 6, 1888.

16,025. S. Bunting. Dublin. Improvements in automatic measuring, supply and delivery of air, gas, electricity and like force; also liquids, by the introduction of a coin or any given weight. November 6, 1888.

16,047. W. P. Thompson. Liverpool. Improvements in magneto-electric railway signals (The Pennsylvania Steel Company, United States). November 6, 1888.

16,048. W. P. Thompson. Liverpool. Improvements in or relating to secondary or storage batteries (C. H. Thompson, United States). November 6, 1888.

16,054. C. Wells. London. An improved apparatus for the delivery of electricity. November 6, 1888.

16,099. C. M. Dorman and R. A. Smith. Manchester. Improvements in the construction of electrical switches, cut-outs, ceiling and wall connectors. November 7, 1888.

16,129. J. E. Lansard. London. An improvement in the contact makers of electrical alarms for doors and windows. November 7, 1888.

16,140. E. Tyer. London. Improvements in the charging of secondary electric batteries from primary batteries, and apparatus for the purpose. November 7, 1888.

16,146. F. Moreton. London. Improvements relating to electro-medical batteries. November 7, 1888.

16,202. J. J. Hine. London. Improvement in and connected with electrical billiard marking apparatus. November 8, 1888.

15,217. W. Lowrie, C. J. Hall and H. W. Kolle. London. Improvements in measuring alternating currents of electricity. November 8, 1887.

16,398. B. W. Warwick. London. Automatic machines for the supply of liquids on draught by electrical and other means. November 29, 1887.

16,790. S. C. Hanberg. London. Improvements in dynamo-electric machines. December 6, 1887.

16,807. D. Urquhart. London. Improvements in or connected with incandescent electric lamps. December 6, 1887.

17,582. E. F. H. H. Lauckert. London. Apparatus for indicating the time during which electricity is used for lighting or other purposes. December 21, 1887.

17,641. J. E. Wright and J. Moore. London. Improvements in printing telegraphs. December 22, 1887.

17,807. F. L. Rawson, of and on behalf of the Woodhouse and Rawson Electric Manufacturing Company (Limited). London. Improvements in the construction of rheostats or similar electrical instruments (C. Wirt, New York). December 27, 1887.

203. O. C. D. Ross. London. Improvements in the utilisation of waste products from electrical batteries. January 5, 1888.

295. T. Parker, of the firm of Elwell-Parker (Limited), and E. Rees. Manchester. A new or improved electric meter. January 7, 1888.

1,016. A. M. Taylor. London. An improvement in electrical transforming apparatus. January 23, 1888.

1,105. W. Webster, jun. London. Improvements in the means or appliances for treating sewage by electrolytic action and for disposing of the deposits thereof. January 24, 1888.

2,259. H. Mestern. London. Improvements in thermo-electric and furnace batteries. February 14, 1888.

10,415. C. Gassner, jun. London. Improvements in the manufacture of electrical dry elements. July 18, 1888.

12,066. A. J. Boult. London. Improvements in or relating to electrical type writers capable of being used as printing telegraphs (J. F. McLaughlin, United States). August 21, 1888.

12,754. H. H. Lake. London. Improvements relating to electric bells, and to indicating apparatus for use in connection therewith (W. Humans, United States). September 4, 1888.

13,122. E. J. Paterson and C. F. Cooper. London. Improvements in the armatures of dynamo-electric machines. September 11, 1888.

14,522. D. Humphreys. London. Improvements in galvanic batteries. October 9, 1888.

November 17, 1888.

15,878A. V. Popp. London. New or improved apparatus for measuring the time during which a current of electricity or other fluid is flowing. November 18, 1887. [Note.—This application, having been originally included in No. 15,878, dated November 18, 1887, takes, under Patent Rule 23, that date.]

17,502. G. Hookham. Birmingham. Improvements in electricity meters, parts of which improvements are applicable to dynamo-electric generators and motors. December 20, 1887.

296. T. Parker, of the firm of Elwell-Parker (Limited). Manchester. Improvements in switches for electric circuits. January 7, 1888.

472. W. Webster, Jun. London. Improvements in apparatus for treating sewage and other impure liquids by electrolysis. January 11, 1888.

584. W. L. Madgen. London. Improvements in the method of and apparatus for supplying electric railways or tramways with electricity. January 13, 1888.

1,557. F. Jacob. London. Improvements in duplex telegraphy. February 2, 1888.

4,673A. P. M. Justice. London. Improvements in and relating to switch and cut-out apparatus for incandescent electric lamps (C. Heisler, United States). March 27, 1888. [Note.—This application, having been originally included in No. 4,673, dated March 27, 1888, takes, under Patents Rule 23, that date.]

6,093. F. Jacob. London. Improvements in Morse inker apparatus for telegraphic purposes. April 24, 1888.

12,063. A. J. Boult. London. Improvements in or relating to electrical typewriters capable of being used as printing telegraphs (J. F. McLaughlin, United States). August 21, 1888.

12,064. A. J. Boult. London. Improvements in or relating to electrical typewriters capable of being used as printing telegraphs (J. F. McLaughlin, United States). August 21, 1888.

12,065. A. J. Boult. London. Improvements in or relating to electrical typewriters capable of being used as printing telegraphs (J. F. McLaughlin, United States). August 21, 1888.

12,453. W. P. Thompson. Liverpool. Improvements in apparatus for hardening and tempering by electricity (P. Diehl, United States). August 29, 188 .

14,492. J. B. Sutherland. London. Improvements in electrical signalling, indicating or registering apparatus for railway purposes. October 9, 1888.

14,691. T. N. Vail and J. A. Seely. London. Improvements in telephone central station apparatus. [Date applied for under Section 103 of the Patents, &c., Act, 1883, April 20, 1888.] October 12, 1888.

PATENTS SEALED.

November 9, 1888.

3,533. A. M. Clark. London. Improvements in electric railway signalling apparatus (J. D. Gould, United States). March 8, 1887.

13,960. A. Coleman, Edgbaston, and H. F. Jackson, Sydenham. A novel combination of spring-jack and lightning arrester, for use in or with a test-board, for telephone wires and means of carrying, and a method of arranging any required number of sets or apparatus formed of such combination, such invention being applicable also for the purpose of a telephone switch-board, and for other analogous electrical purposes. October 14, 1887.

14,658. G. E. Fletcher. Stockport. Improvements in electric indicators. October 28, 1887.

6,614. E. G. Craven. London. Improvements in the electrical illumination of clock dials and apparatus in connection therewith. May 3, 1888.

10,691. A. J. Boult. London. Improvements in or relating to electrical transmitting instruments (J. F. McLaughlin, United States). July 24, 1888.

NEW COMPANIES REGISTERED.

THE DOUGLAS PATENT CLOCK AND ELECTRIC METER COMPANY (LIMITED).—Registered by Waterlow Brothers and Layton (Limited), with a capital of £10,000, in shares of £10 each. Object: to purchase or otherwise acquire and undertake the business of manufacturers of the patent detached pendulum and other clocks, and of meters for the measurement of electric currents, now carried on at 93, Vyse-street, Birmingham, under the firm of the Douglas Patent Clock Company, and to acquire all and every of the assets and liabilities of the said firm in relation to the said business, and with a view thereto to adopt and carry into effect, with or without modification, an agreement dated October 25, 1888, and made between William Henry Douglas, Edwin Lewis Gyde and George William Whitehouse of the one part, and John William Wall, on his own behalf and as trustee for the company, on the other part; to carry on business as manufacturers and factors of the said annual clock and electric meter, and any business of a like or kindred character to that now carried on by the Douglas Patent Clock Company. The first subscribers are:—

	Shares.
W. H. Douglas, High-street, Stourbridge	30
E. L. Gyde, Soho-hill, Handsworth, Birmingham	30
G. W. Whitehouse, Hylton-street, Birmingham	30
T. Parker, Newbridge, Wolverhampton	30
J. Moseley, Cringle Hall, Levenshulme, Manchester	30
H. P. Holt, The Cedars, Dewsbury	30
S. W. Page, The Poplars, Penn Fields, Wolverhampton	1

The first directors shall be Thomas Parker, Edwin Lewis Gyde, George William Whitehouse and William Henry Douglas. The qualification of every director shall be the holding of 30 shares in the capital of the company. The remuneration of directors shall be determined in general meeting. William Henry Douglas shall be the first managing director of the company.

LANCASHIRE ELECTRIC AND ENGINEERING COMPANY (LIMITED).—This company was registered on the 8th inst., with a capital of £20,000, in shares of £5 each, to carry on at Bolton and elsewhere, the businesses of mechanical, hydraulic and general engineers and machine makers, electricians, electrical engineers and workers and dealers in electric and other motive power and light. The first subscribers are:—

	Shares.
*M. Settle, Snow-hill, Darcy Lever, colliery proprietor	1
*J. Atherton, Bolton, mining surveyor	1
*J. Tonge, Westhoughton, mining engineer	1
*G. H. Peace, Tyldesley, mining engineer	1
*G. Crowther, Bolton, mining engineer	1
J. C. Sewell, Bolton, electrical engineer	1
F. W. Briscoe, Bolton, accountant	1

There is not to be less than 5, nor more than 7 directors, and the first are the subscribers denoted by an asterisk; qualification, 10 shares.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended November 16th, 1888, amounted to £5,456.

EASTERN TELEGRAPH COMPANY.—Sir Albert Cappel, K.C.I.E., late Director-General of Telegraphs in India, has joined the Board of this company.

WEST AFRICAN TELEGRAPH COMPANY.—The offices of this company have been removed from 93, Cannon-street, E.C., to Winchester House, 50, Old Broad-street, E.C.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended November 16th, 1888 (after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, Limited), were £4,495.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The traffic receipts for the half-month ended November 15th, 1888, were £2,314, as compared with £2,625 in the corresponding period of 1887, a decrease of £311, July recespts, estimated at £5,331, realised £5,402.

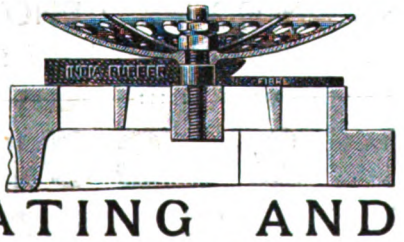
UNITED TELEPHONE COMPANY (LIMITED).—The directors recommend an interim dividend of 5s. per share, being at the rate of 10 per cent. per annum, the same as a year ago.

NOTICES OF REMOVAL.—Messrs. W. T. Goolden and Co. announce that they have removed their offices from 2, Victoria-mansions, Westminster, and their works from Westminster and Halifax, and that in future their only address will be Woodfield-road, Harrow-road, London, W.

——— Messrs. Harvey and Peak have removed from their old address, Beak-street, Regent-street, W., to 6, Sandringham-buildings, Charing Cross-road, London, W.C.

NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature. Suitable for any shaped guards. Only one quality manufactured.

"12, John-street, Sunderland, 26th Sept., 1885.
"DEAR SIRS,—In reply to your letter of the 25th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue to get them from you as required.—Yours faithfully, JAMES WESTOLL."

For further Testimony and Prices, apply to **MOSSES & MITCHELL, 68-71, Chiswell Street, London.**

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 550.—Vol. XXII. FRIDAY, NOVEMBER 30, 1888. Price 4d.

NOTES.

We publish this week, from the pen of Mr. Preece, a most interesting Paper, written thirty-four years ago, containing an account of some experiments on the retardation of signals on underground telegraph circuits, in which Faraday, Latimer Clark and Sir George Airy were engaged.

We have received from the Chelsea Electric Supply Company a copy of a memorial which has been addressed by them to the Chelsea Vestry with regard to an application on the part of the London Electric Supply Corporation for permission to carry an underground main through the centre of the Chelsea district. It will be recollected that the first-named company is in possession of an Act of Parliament confirming a Provisional Order for lighting this district; they have already deposited with the Board of Trade the required guarantee (£2,000), and are now at work upon the mains. Under these circumstances the protest contained in the memorial is a not unreasonable one, and it is certainly of equal importance to all parties concerned that the precise degree of monopoly conferred by a Provisional Order should be speedily made known. It is desirable, also, that the extent of the powers vested in the Board of Trade, and the precise line of demarcation between its jurisdiction and that of the local authority, should be more clearly defined. We have already pointed out that, as a matter of fact, the powers of the Board of Trade are very nearly absolute when once a company has come within its cognisance either by License or by Provisional Order, and the present case appears to afford a good opportunity for ascertaining the scope of their authority over other works within a scheduled district. We may add that we have reason to believe that the Board may before long be expected to make some pronouncement in the matter of overhead wires.

It will be generally admitted that the perfection of alternate-current motors is at the present time the most pressing and the most important problem with which the attention of electrical engineers is occupied. The Tesla motor, in the hands of the Westinghouse Company, even if it does not at this moment present a final solution of the problem, does certainly possess so many and such striking advantages that we may be quite certain that no effort will be spared to bring it to perfection. At present, however, we believe that the difficulty of making it self-starting, which was referred to at some length by Mr. W. J. Swinburne, in *The Electrician* of July 20th, 1888, has not been altogether overcome. There is also the disadvantage of the double main. In the Westinghouse system, however, it happens that this is of comparatively small importance—and for this reason, the Westinghouse Company, working at only 1,000 volts in the primary, prefers to restrict its circuits to a maximum load of about 1,500 lamps. Hence it will be comparatively easy to arrange to bring two separate circuits run from separate machines at the necessary quarter-phase interval into any given locality. The motor can then be run off two distinct lighting circuits without additional expense in leads.

On the question of working motors of this type from a single pair of mains we may recommend those interested to re-read the Paper of Prof. Galileo Ferraris, an abstract of which appeared in *The Electrician* of May 25, 1888, a date antecedent, by-the-bye, to the publication in this country of Mr. Tesla's independent work in the same direction. Prof. Ferraris proposed to overcome the difficulty by exciting the field of the motor by means of a transformer wound with one primary and two secondary coils. In one secondary circuit he would place as much inductance and as little resistance as possible, and in the other he would have little inductance and as great a resistance as might be necessary. In this way the phase of the two secondary currents would be displaced by an amount tending in the limit to 90 degrees. The method must be to some extent wasteful of energy, but we may suggest that in practice it might prove sufficient to connect one set of field coils in parallel and the other set in series. Those coils which are to be connected in series would have to be of large wire, so as to reduce the resistance as much as possible, and those which are in parallel would either be of finer wire or else a non-inductive resistance would be inserted. Since we should be working from a transformer it would be easy enough to adjust the voltages, but whether it would be possible to carry this principle far enough to obtain a displacement of phase sufficient for economical working is a question upon which we hazard no opinion at present. There are doubtless other ways of obtaining the same end—such as the use of impedance coils—but we strongly suspect that all the more obvious of these devices have already been tried at Pittsburg, and have been found wanting.

At the meeting of the Society of Telegraph Engineers last week, Mr. Edmunds' Paper "On a New System of Electrical Distribution" did not lead to any very lively discussion. The

Digitized by Google

compliments which were paid to the ingenuity of the inventor were doubtless both sincerely meant and thoroughly well deserved; but nevertheless there was an unmistakable feeling that as yet the time had hardly arrived for a recognition of the system as a practicable and commercial method of distribution. In fact, the almost total absence of figures, especially as to the first cost of the "distributor"—one of which, it must be remembered, Mr. EDMUNDS proposes to place in every house—could not fail to give an air of unreality to the whole thing. Opinions were freely expressed at the close of the meeting that the apparatus could not be made for less than £50 or £60 apiece; and if this be anywhere near the mark, it seems scarcely worth while to discuss the chances of its satisfactory working, or the advantages of the intermittent method of charging accumulators. It must also be noted that the first cost of the batteries is increased by 33 per cent. over the ordinary B.T. system. If Mr. EDMUNDS' system should really prove its ability to rise superior to such considerations as these, then it will be difficult to award him too high praise; but at the present moment we must be pardoned if we regard the system rather as a brilliant *tour de force* than as a substantial addition to the resources of electrical engineering.

ONE of the most interesting of the many interesting features which this *tour de force* presents is the method of maintaining the current constant by the simple provision of a constant magnetic field in the dynamo with constant steam pressure in the cylinders, and a consequent automatic variation of the speed of the engine. Mr. KAPP takes exception to this method on the ground of the want of economy in coal when the engine is running at its slowest. At the Cadogan Central Lighting Station (which was described in *The Electrician* of July 20th, 1888) this objection is to a great extent overcome by the employment of three engines and dynamos, which are run in series for the full load, so that only one-third of the steam plant is ever worked under uneconomical conditions. Mr. KAPP, and some of the other speakers as well, were apparently under some misapprehension as to the way in which the batteries are actually used—a misapprehension which led them to question Mr. EDMUNDS' claim that the generating plant need be only equivalent to one-third of the total output. The mere fact that Mr. EDMUNDS proposes to run his engine 24 hours per diem shows that it is incorrect to suppose that the batteries "are not allowed to accumulate a charge." On the contrary, the idea is that at the commencement of the hours of lighting the whole of the batteries are more or less fully charged. And since they are on the charging circuit for only two minutes to every six minutes of discharge, the tendency during the period of full load is to run them down. The "hand-to-mouth" principle to which some of the speakers referred is not a feature of the system, and would not under the circumstances be practicable, unless indeed the cells received their charge at three times the rate of discharge.

ONE other feature of the Edmunds system, to which we are rather surprised that no reference was made either in the Paper or in the discussion, is the fact that in order to utilise the current of 70 amperes on the charging circuit throughout the whole installation the cells must all have the same capacity. In the smaller installations, therefore, the number of cells is diminished, and lamps of lower voltage are made use of. This arrangement tends to relatively diminish the cost of small installations, but the multiplication of lamp voltages is not advantageous.

POSSIBLY the most valuable—and, at any rate, the most novel—contribution to the general stock of knowledge which was elicited during the discussion is contained in a remark by Mr. W. H. PREECE. Referring to the fact that a battery discharges itself at a lower voltage than that at which it is charged, Mr. PREECE said, truly enough, that "the general impression of the great majority of men in that room was that under these circumstances they got a great loss of energy." We confess that we have hitherto shared this impression. It appears, however, that this is not so; although we are afraid that we do not as yet clearly comprehend how it comes to be otherwise. Everyone is of course familiar with the fact that the resistance of a cell decreases as the *charge* is increased, so that a well-conditioned cell has an internal resistance about one-half as great when fully charged as when nearly discharged. But Mr. PREECE has recently discovered that during the discharge the internal resistance varies approximately inversely as the current. If so, it might be supposed that we should get a higher efficiency the more rapidly the discharge takes place. Yet Mr. PREECE, in recounting an instance of a 98 per cent. efficiency, says that this was obtained with a discharge of only one ampere. Possibly the present confusion of our ideas upon the subject is sufficiently accounted for by the bare mention of a 98 per cent. efficiency, and when we have become somewhat more accustomed to this degree of magnificence we shall be better able to understand the argument. Meanwhile we feel decidedly fogged.

THE Paper read by Prof. RÜCKER at the last meeting of the Physical Society, and of which an abstract will be found in another column, forms a most important contribution to the difficult subject of physical units, and we cordially re-echo the hope expressed by Prof. CAREY FOSTER at the meeting, that the Paper may be adequately discussed when it has been printed *in extenso*. There are few students to be found whose minds are not in a hopeless fog on the subject of the dimensions of electrical and magnetic units expressed in the two systems in practical use, and, as Prof. AYRTON pointed out during the discussion, there is evidence that this fog has not been entirely dissipated from the minds of many of those to whom students turn for instruction. Prof. RÜCKER's suggestions appear to provide an efficient means for clearing the mental atmosphere in this respect, and, as such, we would commend them to the careful attention of students and physicists alike.

WE are pleased—though not surprised—to find that the views which we expressed last week as to the coupling of cells for electric traction are fully shared by no less an authority than Mr. A. RECKENZAUN. We understand that in his designs for electric tramcars Mr. RECKENZAUN never allows the cells

Digitized by Google

to be placed in parallel. It would be interesting to learn exactly how many accumulator cells were knocked up from this cause in the electric launches which appeared last year on the Thames. It is satisfactory to know that the experience gained has not been of so unfavourable a character as to damp the ardour of those engaged in the enterprise, for at the present time we know of nearly a dozen launches which are under construction. And if the practice of coupling cells in parallel is abandoned we are satisfied that results of a far more encouraging character will next season be obtained.

ONCE more we enter upon a period of electrical litigation. The case of King, Brown and Co. *v.* The Anglo-American Brush Corporation, in which the pursuers seek to annul the compound-winding patent now held by the defenders, came before the Edinburgh Court of Session on Tuesday last, and is being specially reported for *The Electrician*. It may be as well to note that the Mr. HADDAN whose name is prominent in the proceedings is the "Cheesebrough" of compound-winding; that is to say HADDAN is the name of the Patent Agent who received "a communication from abroad" containing the patent specification now in dispute. Edison and Swan *v.* Holland and Others comes before the Court of Appeal within the next few days, and will be immediately followed in the same Court by Ferranti *v.* Gaulard-Gibbs.

THE promoters of the Mining and General Electric Light Company, the prospectus of which has been issued this week, estimate that if the sale of their portable storage battery lamp reaches "only 80,000" per annum, a profit of 15 per cent. on a capital of £100,000 will be forthcoming. This is a proposition which we need not dispute. Nevertheless, we do not believe that it can be held to justify the payment of such an exorbitant sum as £80,000 (£46,000 in cash) for the patent rights. The lamp is said to weigh 5lb., for about six hours' burning, and to cost £1. But we fail to understand what security exists that the invention (if invention it be) approximates near enough to perfection to justify a price which would be reasonable only in the case of an entire monopoly of the business.

WE learn from the Moscow *Technik* that M. BEKETOV, of Charkoff, has succeeded in the economical production of metallic sodium by the electrolysis of the fused chloride (common salt). If the process should prove to give satisfactory results on a large scale of working it may very probably have a future of some importance in connection with the St. Clair Deville process for the manufacture of aluminium, in which the preparation of metallic sodium is at present one of the most costly stages. At the fusing temperature of sodium chloride (500° C.) it possesses considerable conductivity. The electrolysis is effected in a cylinder of earthenware. The electrodes are introduced at either end, passing through porcelain tubes which extend beyond the poles on the inner side. The positive electrode is of carbon, and the negative of iron. The latter is pierced longitudinally by a canal, through which the metallic sodium continually runs away. The method of carrying off the chlorine is not described, but probably it presents no difficulty. The fused salt is introduced from time to time by an opening at the centre of the chamber. With a current of 16,000 amperes under an E.M.F. of 5 volts (or about 120 horse-power) 50 pouds (or about 1,800lb.) of salt can be decomposed in twenty-four hours, yielding 720lb. of the metal and 1,080lb. of chlorine. Assuming that about five tons of coal are consumed, it will be evident that at the present value of sodium, to say nothing of the chlorine, the process ought to yield a very handsome profit.

THE *United Service Gazette* is responsible for the following:—"The dockyard authorities have been asked to report on the advisability of lighting the dockyards throughout by electricity, using Ferranti's system of a central station and transformers. At Portsmouth it was suggested that the central pumping station might be utilised to generate the electricity. But there is yet comfort for the Portsmouth Gas Company. The dockyard officers reported they did not consider that Ferranti's system was sufficiently perfected at present, and that when the pumping station was pumping out a dock, there would not be sufficient power to spare for lighting purposes."

A New Technical Journal.—We understand that a new fortnightly electrical journal will appear, at the beginning of the new year, under the title of "THE TELEPHONE."

The Elmore Process.—We understand that Messrs. Woodhouse and Rawson have taken up the Elmore process of manufacturing copper wire, and will shortly be prepared to supply wire of this description.

Cable Ships and Cricket.—A cricket match was played recently at Cape Town between the combined teams of the cable ships "Great Northern" and "Amber" and the Garrison team, which resulted in an easy victory for the latter. The scores are not to hand.

Oldham.—Messrs. John Barker and Sons (Limited), engineers, Oldham, have decided to light their new foundry works by electricity. The Lever system has been selected, and the order has been placed in the hands of Mr. Charles Lever, of Bowdon, Cheshire.

Morecambe.—At the last meeting of the Local Board a notice was read from Messrs. Andrews and Preece, dated 29th October, 1888, stating their intention to apply for a provisional order authorising the supply of electricity within the district. It was resolved unanimously that the question of lighting the district by electricity be recommended to the Board for consideration.

The British Electric Light Company.—The scheme of arrangement for resuscitating the British Electric Light Company has been sanctioned by the Court, and a circular is now being issued requesting the creditors of the company to send in particulars of their claims in order that preference shares may be issued to them in accordance with the terms of the scheme.

A Submarine Cable Concession.—The Dutch authorities have granted a sixty years' concession to the Pedro Segundo Cable Company to lay and work submarine cables between Willemstad (Curaçoa), Paramito (Surinam) and Vizen (Brazil). The cables are to be laid within eighteen months, and an annual subsidy of 20,000 florins will be paid to the company for the first twenty years.

Digitized by Google

Buckingham Palace.—We understand that the hall at Buckingham Palace is to be fitted with the electric light before next season, but the Queen will not allow the light to be introduced into the private apartments at Windsor Castle, as her Majesty prefers shaded lamps and wax candles. The State apartments, the hall, and the lower end of the corridor are fitted with electric light, but it is to go no further at present.

St. James's Vestry.—A special meeting of the St. James's Vestry was held on Thursday morning, Mr. John Bonthron presiding, at which it was decided, at the instance of Mr. William Jenkins, to consent to the application by the Metropolitan Electric Supply Company (Limited), to the Board of Trade for a provisional order to supply electricity in the parish. An application by the House to House Electric Supply Company was referred to committee.

Newington Vestry.—At a meeting of the Newington Vestry on Wednesday evening, the Rector (the Rev. G. T. Palmer, M.A.,) presiding, an application was made by the House to House Electric Light Supply Company for permission to apply to the Board of Trade for a provisional order to light the district. Consent, it may be mentioned, has already been given for the application for provisional orders by three other companies. The letter was referred to the General Purposes Committee.

The Electric Light at the Glasgow Post Office.—About eight o'clock on Monday night last, according to the *Standard*, the *employés* in the Glasgow Post Office were surprised to find all the electric lights suddenly go out. It was next reported that a fire was seen on the roof. The clerks ran out the hose, and were doing their best to extinguish the flames when the brigade arrived, and in a few minutes the outbreak was got under. The fire was caused, it is said, by some defect in connection with the electric lighting apparatus.

The House-to-House Electric Lighting Company at Brompton.—It is announced that the Central Lighting Station of this company at Brompton (on the Lowrie-Hall system) is expected to be ready for work by the middle of December. The following tariff has been fixed:—At the rate of 1s. per Board of Trade unit for the first 100 hours; 8d. per Board of Trade unit for the second 100 hours; 4d. per Board of Trade unit for any further quantity consumed. Rent of meter, instruments, &c., 5s. per Board of Trade unit per quarter.

E.P.S Smoking Concert.—The Electrical Power Storage Company held, what we understand is the first, of a series of smoking concerts in connection with their cricket club, on Monday evening, at the Eastern Hotel, Limehouse, near their works. In the unavoidable absence of Sir Daniel Cooper, the chair was taken by Mr. John Irving Courtenay, the managing director of the company. The programme was of a varied and attractive character, and was rendered in a highly successful manner. Many of the friends of the E.P.S. Company as well as the *employés* were present.

St. Martin-in-the-Field Vestry.—At the last meeting of this Vestry a letter was read from the London Electric Supply Corporation, requesting permission to lay an underground main in Durham-street from the Adelphi-arches, across the Strand to the passage leading to the premises of the Corps of Commissionaires, and enclosing draft of an agreement for that purpose; and the Clerk having reported that the agreement had been so drafted as sufficiently to protect the interests of the Vestry, the committee recommended that the draft be approved, and an agreement be entered into with the Corporation in accordance therewith. This was agreed to.

Wood Casing for Electric Wires.—Messrs. J. F. and G. Harris (of 56 and 60, Wilson-street, Finsbury) send for our inspection some very excellent white wood moulding, designed especially for casing electric light wires of various sizes. This firm are large dealers in wood and timber, and they pay special attention to machine mouldings of every description. Having a large connection amongst builders and wholesale shippers, Messrs. Harris possess every facility for turning out large quantities of material at short notice, and they should also be able to compete successfully with their rivals in the matter of price. The mouldings sent to us are of handsome appearance, and, being finished with a beading on the inner edge of the cone, the joints are invisible.

The Anglo-American Brush Electric Light Corporation (Limited) have just booked an important order from the Pacific Steamship Company for several of their plants of combined engines and dynamos, specially designed for use on board ship. We hear that the company is also exceedingly busy with general orders, and its prospects seem very encouraging. The important contract which it entered into some time since for the lighting of the Glasgow Exhibition has just been completed, to the entire satisfaction of the executive committee of the exhibition. As we also note elsewhere, the Brush Corporation have been awarded a gold medal for their electric fountain display at the Barcelona Exhibition, and a diploma of honour for electric lighting at Brussels.

A Crew Disabled by Lightning.—The Guion Line steamer "Alaska," from New York, brings intelligence of the ship "Edward," from Havre, with a cargo of iron ore, whose captain reported that the vessel encountered a terrible storm in the Atlantic on the night of the 31st ult. The vessel was continuously enveloped in lightning, which prostrated on the deck eleven seamen, and deprived them of sight for nearly half a day. The second officer and the boatswain were also dashed to the deck, and received serious injury. Three balls of fire exploded with a tremendous report over the main rigging, scattering flaming fragments over the ship, and driving the remaining members of the crew in terror into the forecastle. From 3 a.m. until 7 p.m. the captain and mate were the only persons on board capable of doing any work.

St. Margaret's and St. John's Vestry.—At a meeting of the St. Margaret's and St. John's Vestry (Westminster), on Wednesday afternoon, Mr. H. Bowman Spink presiding, the Parliamentary Committee reported that they had considered the reference on the question of the desirability of the Vestry applying for a licence or provisional order for the lighting of the parish by electricity; but, having regard to circumstances generally, they did not think it would be expedient for the Vestry to do so at the present time. The following resolution was eventually agreed to: "That the recommendation now submitted be referred back to the Parliamentary Committee, with power to fully inquire into the whole question of electric lighting, and with authority to inquire of the lighting corporations of London and the provinces, the committee to have leave also to inspect the works of any of the companies in or near London formed for the purpose of supplying the light."

Opening of the Derby Telephone Exchange.—The National Telephone Company opened a Telephone Exchange in Derby on Monday afternoon last. The Exchange opens with a membership of about 20. When the company's line from Birmingham to London is completed, Derby will be placed in direct communication with the metropolis. Through communication with the great Yorkshire towns will also be made in a few weeks. The formal ceremony of opening the Exchange was performed at the Lecture Hall, in the Wardwick, where a large number of persons assembled. Ald. Roe, M.P., proceeded to formally declare the Exchange open, adding that he wished it

Digitized by Google

every success. The gentlemen present then adjourned to the ante rooms, into which several wires connecting with the trunk lines had been introduced. They there heard musical performances in Birmingham, Sheffield, and Nottingham, and many of the party afterwards visited the head-quarters of the Exchange in Becket Well-lane.

Electricity and Underground Haulage.—At a meeting of Mining Engineers in South Wales, held last week, Mr. J. Fox Tallis read a Paper on "The Application of Electricity to Underground Haulage." It was patent, the writer observed, that the old servants, steam, air, and water, were limited in their scope of adapting themselves to existing and future circumstances. Colliery proprietors would be the first to admit the inadequacy of present systems to meet the requirements of to-day, and would be the first to appreciate and adopt an improved system that offered greater facilities of transmission over longer districts and more extended areas. Electricity, he contended, had the advantages of being more easily and economically subdivided into a number of paths, fewer moving parts, small and fixed mains, less liability to injury, less space, and greater efficiency. The Paper did not go into the subject of locomotive motors, as the writer did not consider them practicable, but claimed that the electric motor was the best means for underground hauling. The Paper was ordered to be printed for discussion at the next meeting.

Electric Light in the Dockyards.—Although the electric light has not superseded gas in the Dockyards, says the *United Service Gazette*, it has been extremely useful as an additional illuminant where gas could not conveniently or safely be used. The old custom, when men were working under ships' bottoms in dock, was to have what were well called "stink pots"—that is, iron pots containing tallow and oakum, which took two men to look after them, and made more smoke than light. Then innumerable candles were used in the double bottoms and other interior portions of ships building. It will easily be understood that these did little more than make darkness visible, so that the inspection of work before the advent of electricity was a very tedious business. Now, each ship of any size, as soon as it is launched, has an electric light engine placed on the upper deck, and strings of incandescent lights are placed in any part of the ship where work is going on. Before she is launched, as soon as the light is required, it is provided from an engine which supplies one or two ships, according to size. By this means work is done much better than it would be if completed in semi-darkness, and efficient supervision can be constantly exercised.

Formation of an "Electrical Institute of New South Wales."—We have received the following very interesting communication by the last mail from Australia:—"Sir: It may perhaps interest you to hear of the formation of this institute, which has now been in existence some three months. The project was started by five of us, and at the time of writing we have fifty-four members. We have been able to secure rooms in a central part of the city, which are open daily from 10 a.m. to 11 p.m., and supplied with various papers, including *The Electrician*, *Electrical Review*, *Engineering*, *Engineer*, *Nature*, *Building and Engineering Journal of New South Wales*, &c. The last-named paper has offered to print all our Papers and discussions for us free. So far five Papers have been read at the fortnightly meetings, which have provoked much interesting discussion. I enclose a copy of our rules, containing also a list of members up to the date of printing. It is to be hoped that the institute will fulfil its object in promoting good feeling between the members of our profession out here, for up till now there has been a great want of that friendly intercourse so pleasant at home.—Yours, &c., E. R. Dymond, Stud. Inst. C.E., Acting Sec."

The Areas of Electric Lighting.—The following letter appeared in the last number of the *Municipal Review*:—"Sir: A typical debate on the above subject, on which a few words may not be out of place, took place at the Kensington Vestry on the 14th inst. The point on which the discussion hinged is sure to arise in other districts. It is therefore one of more than local interest. A committee of the Vestry excluded from consideration the application of a most solvent and influential electric lighting company for permission to apply to Parliament for a provisional order to light a portion of the parish of Kensington. The exclusion was based avowedly on the ground that, inasmuch as the works of the company were situated in another parish, it would be inexpedient to permit the company to light Kensington. For, it was argued by the committee, if at any time hereafter Kensington should decide to supply itself with electric light, the fact that the works of the company owning the Kensington wires were not situated in Kensington would be an insuperable bar to the scheme. For how, it was urged, could the wires be bought without the works from which they were fed, and how could one parish buy property situated in another, over which the first parish had no control? I venture to say, sir, that I can supply two answers, either of which, as I submit, disposes of the committee's argument. First, Kensington can, and does, own property in other parishes. For instance, a wharf in Hammersmith and a dust-shoot at Purfleet. Secondly, the Committee's objection only proves the inadvisability of mere parishes or districts, which are but fragments of London, owning such properties at all. The new County Council clearly is not open to the same objection.—I am, sir, yours, &c., James F. Torr."

The Lighting of Cowpen.—At a meeting of the Cowpen Local Board, held at the beginning of the month, a deputation from the Blyth Gas Company explained to the Board the lowest terms at which the gas company could afford to light the district. A representative of Messrs. Nicholson and Jennings, of London, then had an interview with the Board. He said they were prepared to light the town for £600 a year; he gave it as his opinion that eighteen electric lamps would suffice. The shortest period for which his company would tender was seven years. An adjourned meeting of the Local Board was held on the 13th inst. to consider the matters referred to above. After some discussion it was proposed that a committee be appointed to confer with the electric light company to see whether a shorter term than seven years could not be arranged for a contract. The words, "and with the gas and oil companies," having been inserted, the motion was carried. At a special meeting of the Local Board on Wednesday, 21st, the public lighting question was again under consideration. The chairman reported that the committee appointed at the last meeting of the Board had fully considered the subject of public lighting, and had come to the conclusion to recommend the Board to make an offer to Messrs. Nicholson and Jennings. They were to be asked to supply electricity at the rate of £550 per lighting season for 18 arc lamps of 2,000 candle-power, for a period of five years, subject to conditions and arrangements to be mutually agreed upon; the work to be satisfactorily completed within a period of two months from the date of signing the contract.—Mr. Whiteman proposed that the words, "Further, that all arrangements and sanctions necessary from the Board of Trade be obtained by contractors," be added to the recommendation of the committee. This proposal having been agreed to, the committee's recommendation was unanimously adopted.

NOTES ON ELECTRO-MAGNETIC INDUCTION.

BY DR. J. A. FLEMING, M.A.

(Continued from page 41.)

Returning to the equations (5) and (6) we can now find the constants of integration, counting the time from the instant of "make" of the primary. It is obvious that when $t = 0$, $y = 0$ and $x = 0$, and that the whole quantity of the make-induced current, or $\int_0^\infty y\,dt$, must be equal to the whole quantity of the break-induced current, which we have seen is equal to $\frac{M\,I}{R}$.

In (6) put $t = 0$, $y = 0$; we get

$$A' + B' = 0, \qquad \text{or } B' = -A'.$$

Hence,
$$y = A\left(e^{-\frac{Rt}{L+M}} - e^{-\frac{Rt}{L-M}}\right)$$

and
$$\int_0^\infty y\,dt = -\frac{2A'M}{R}.$$

Hence the whole quantity of the "make"-induced current is $-\frac{2A'M}{R}$, and this must be equal to $\frac{MI}{R}$, which is the whole quantity of the "break" current. Hence $A' = -\frac{I}{2}$.

Therefore we get for the instantaneous strength of the "make" secondary current

$$y = -\frac{I}{2}\left(e^{-\frac{Rt}{L+M}} - e^{-\frac{Rt}{L-M}}\right) \quad . \quad . \quad . \quad (8)$$

Again in (5) put $t = 0$, $x = 0$,

and we get $A + B + I = 0$,

or $B = -(I + A)$;

and by substitution in (5)

$$x = A\,e^{-\frac{Rt}{L+M}} - (A + I)\,e^{-\frac{R}{L-M}} + I.$$

From this equation we can find the value of A by substituting the value of $\frac{dy}{dt}$ derived from equation (8), and $\frac{dx}{dt}$ derived from the above in the original differential equation (i.), and we find $A = -\frac{I}{2}$. Hence we arrive at the equation for the value of the primary current at any instant, and it is

$$x = I - \frac{I}{2}\left(e^{-\frac{Rt}{L+M}} + e^{-\frac{Rt}{L-M}}\right) \quad . \quad . \quad . \quad (9)$$

This gives the law according to which the primary current grows up in its circuit if $M = 0$; that is, if there is no secondary circuit; then

$$x = I\left(1 - e^{-\frac{Rt}{L}}\right)$$

which is the ordinary law of current growth. If $M = L$, which is the greatest possible value of M, then

$$x = I\left(1 - \frac{1}{2}\,e^{-\frac{Rt}{2L}}\right).$$

Hence it is obvious that the presence of the secondary circuit hastens the rise of the primary current and operates on it to reduce its inductance.

On making the primary we get a "make" or inverse secondary current according to the law of growth expressed by the equation

$$y = -\frac{I}{2}\left(e^{-\frac{Rt}{L+M}} - e^{-\frac{Rt}{L-M}}\right),$$

and we see that under the circumstances assumed the "make" secondary starts from an initial value zero, rises up to a maximum, and then decays away again. To find the time of reaching maximum, equate $\frac{dy}{dt}$ to zero, and we find

$$t' = \frac{L^2 - M^2}{2\,R\,M}\log\left(\frac{L+M}{L-M}\right),$$

and this function *increases* as M *decreases*. So that the more nearly M is equal to L the *sooner* does the secondary reach its maximum. It is not difficult to show that when $M = L$ the above value for t' becomes zero, and when $M = 0$ $t' = \frac{L}{R}$.

If, then, we trace a series of curves (Fig. 11) representing the values of y, or the make-induced current at each instant for various and increasing values of $\frac{L}{M}$ as the coils are moved further apart, we find a series of curves with decreasing maxima, but the maxima happening later as M decreases.

Lastly, on breaking the primary current we have a break-induced current in the same direction as the primary, which, at any instant after the "break," is decaying away according to the law

$$z = \frac{M}{L}\,I\,e^{-\frac{Rt}{L}}.$$

If the break was absolutely instantaneous, the induced current would start with a finite value equal to $\frac{M}{L}$ of that of the primary, but as no form of break entirely eliminates sparking, the rise of the direct secondary current is a gradual one. Also we have another element of disturbance which enters into the case. The self-induction of the primary creates direct electromotive force in its own circuit at the instant when the induction through the primary due to its own current vanishes. When

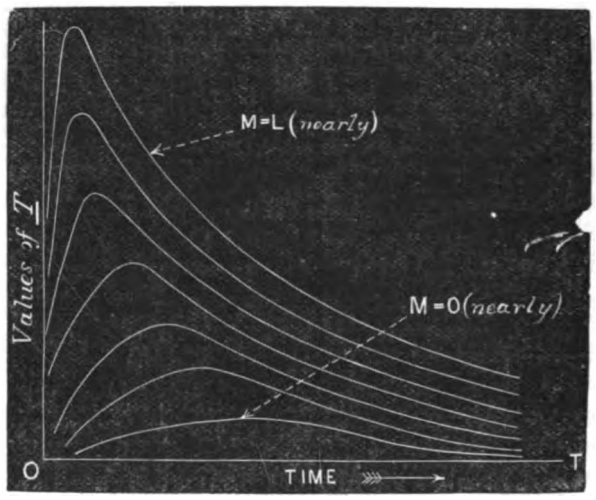

FIG. 11.

Curves representing roughly the current value of the make-induced current for different and increasing values of M.

the primary is broken either at a mercury cup or at a platinum point the fusion and volatilisation of metal which takes place keeps open for a little time a conductive path through which flows the *extra current* due to the self-induction of the primary. This extra current may have at a particular instant a higher value than that of the strength of the steady current, so that for a short instant the primary current may be actually increased on beginning to break the circuit before it commences to decay.

This direct extra current in the primary will have its effect in introducing a very short inverse-induced current, which will precede the main direct-induced current due to the decay of the primary current. In any event it will introduce an electrical oscillation tending to render the growth of the direct secondary current a gradual matter. It is an interesting case to examine the relative maximum values and duration of the two induced currents under an assumption very nearly realised when the primary and secondary are wound together on the same bobbin, viz., when $M = L$. In this case the values of y and z become

$$y = \frac{I}{2}\,e^{-\frac{Rt}{2L}}$$

$$z = I\,e^{-\frac{R}{L}}.$$

Digitized by Google

The maximum of the direct currents ("break") is I, and that of the inverse (or "make") is $\frac{I}{2}$. If we wish to know at the end of what times t and t' the strengths of the two induced currents y and z are reduced to $\frac{1}{m}$ of that of the primary we obtain by substitution of $\frac{1}{m}$ for y and z in the two above equations the following :—

$$\frac{1}{m} = e^{-\frac{Rt}{L}}$$ for the direct-induced current,

and $$\frac{1}{m} = \frac{1}{2} e^{-\frac{Rt'}{2L}}$$ for the inverse-induced current,

and therefore $$\frac{t'}{t} = 2\left(1 - \frac{\log 2}{\log m}\right).$$

We see that t' is always greater than t, and that in proportion as m increases, t' tends towards a limit $2t$, or the inverse current has a duration about double that of the direct secondary. We shall now see how this theory is confirmed by experiment.

(To be continued.)

SELF-INDUCTION AND RETARDATION.

BY W. H. PREECE, F.R.S.

Experiments made at the Strand Office of the Electric Telegraph Co., May 21, 1854.

Length of wire 1,100 *miles (underground.)**

Experiment I.—A repetition of an experiment at Lothbury, showing the jerk or extra deflection of the needle at the moment of interruption, and the reversal of its poles in consequence. This Prof. Faraday attributed to the induction of a current upon itself, but Mr. Latimer Clark considered it to be due to the intense and sudden action of the return current. Power used 560 cells. [Sand battery, viz., zinc-copper H_2SO_4.] (1) Upon charging the wire the needle deflected to A, as shown in Fig. 1; upon discharging it gave a further

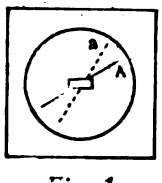

Fig. 1.

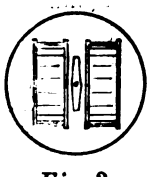

Fig. 2.

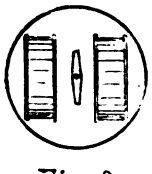

Fig. 3.

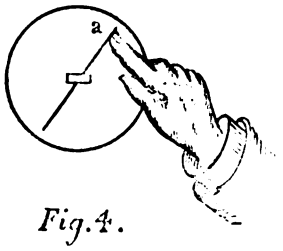

Fig. 4.

jerk to the right and fell back to the vertical, the poles having become completely reversed, for on recharging the wire the needle deflected to the opposite side. This could be repeated at pleasure to the left and right.

(2) Upon increasing the distance of the coils from the needle (*vide* Figs. 2 and 3) and from each other, so as to lessen the power of the current upon the needle and bring it to the dotted position (a), Fig. 1, no such effect occurred. There was no extra deflection and the discharge deflected the needle in the usual direction, viz., contrary to that of the primary current.

(3) Upon examining the needle, taken out while under the influence of the primary current, the coils being closed, and also after the discharge, the polarity in each case was found different.

(4) Upon moving up the needle to the position (a), while under the action of the primary current, and then discharging the wire, no jerk could be perceived upon the finger, and the discharge deflected the needle in the usual direction.

(5) The reversal of the poles and the jerk could only be produced when the needle was deflected above 60 degrees.

These experiments prove beyond doubt that this extra deflection, and consequent reversal of the poles of the needle, is due to the intense and sudden action of the discharge or return current, and not to any extra current induced in the wire by the primary current itself; indeed, in all our experiments upon long wires we can never trace any effects resulting from the induction of a current upon itself.

Experiment II. (Prof. Airy's).—The wires were arranged thus :—

Galvanometers placed at A the "near" end, at B 374 miles off, and at C, the further end, 1,100 miles off. Upon using the intensity of 560 cells, and then of 200 cells, no perceptible difference could be observed in the transmission of the current from the two batteries. It took about eight-tenths of a second after contact was made before any movement could be perceived in needle C. The deflection commenced with a gentle movement, increasing rapidly as the deflection increased (perhaps a little more rapidly with the more intense current, but scarcely perceptible to the eye). The period which each current took to deflect the needle was apparently equal, but the needle fell back in the first case when the intense current was used very much more rapidly than in the second.

Experiment III. (Faraday's).—When a quantity current (large cells) and then an intensity current (small cells) were transmitted along the wire (1,100 miles), each current deflecting the needle to the same extent, no appreciable difference could be perceived in the rapidity of the current, each took about the same time, viz., eight-tenths of a second (using a galvanometer).

Experiment IV. — In the experiments at Lothbury the needle at the distant end was observed to deflect with little jerks or pulsations, not with the steady movement usually observable. This same effect occurred to-day, and in order to

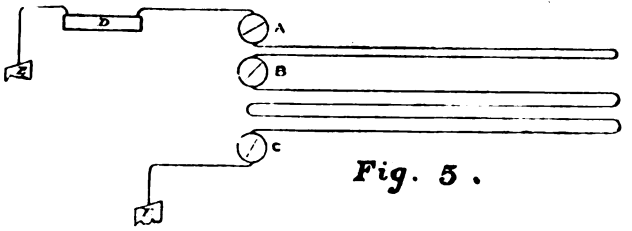

Fig. 5.

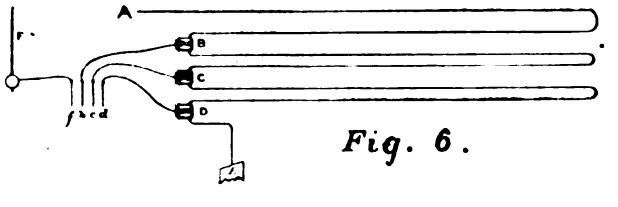

Fig. 6.

test whether it was attributable to an electrical or mechanical cause, I placed a "pecker"* at the distant end in place of the galvanometer. The armature of the pecker was attracted with a steady movement, and showed no signs of pulsations, from which it may be inferred that these pulsations are due to the mechanical movement of the needle, and not to any electrical effect.

Experiment V.—In order to record more accurately the results of experiment (2) I made use of the following arrangement :—

At B, C and D peckers were placed which by the attractions

* These experiments were made for Mr. Latimer Clark on some underground wires which were laid down in earthenware pipes between London, Manchester, and Liverpool, by the Electric Telegraph Company, along the London and North-Western Railway, in 1853-4.

* In the early days of telegraphy relays were called "peckers," from the peculiar form of the contact points.

Digitized by Google

of their armatures brought into action local currents making marks at *b*, *c*, and *d* by the fine steel wire resting upon chemically prepared paper in the same way as we adopted in Lothbury. The wire *b* was in connection with pecker B 374 miles off, *c* with pecker C 750 miles off, and *d* with D 1,100 miles off. Wire *f* was in connection with a seconds pendulum which made a mark upon the paper at every second, and so measured off the paper into a scale of seconds.

Four currents of 560, 480, 336, and 200 cells were consecutively sent through the wire, and their effects recorded upon the paper revolving beneath the wires or needles *b*, *c*, and *d*. The contacts at A were too irregular to enable us to record with any accuracy the periods of transmission between A and B. We must therefore only rely upon the other lengths, viz., between B and C, and C and D. There appears to be a small variation in the times of the appearance of the different currents, but this variation is so irregular, and apparently following no direct law, that we may rather consider it due to the imperfection of our instruments than to any difference in the velocity of the currents. We may consider the times of transmission of all these currents to be equal, as was also observed with the galvanometer; but there is this remarkable difference between the appearance upon the electromagnet and upon the needle—that, while the current upon the one (the needle) appeared in eight-tenths of a second, it did not appear upon the electromagnet for nearly 3 seconds!

N.B.—This experiment was subsequently repeated with greater care, and with Bain's chemical recording instruments. The results were completely confirmed, and submitted to Faraday by Mr. Latimer Clark.

[The above experiments have not appeared in print before, and I publish them now in order that it may be seen how early in the history of the practical application of electricity our attention was directed to self-induction. W. H. P.]

ON THE MAGNETISATION OF IRON AND OTHER MAGNETIC METALS IN VERY STRONG FIELDS.*

BY J. A. EWING, B.SC., F.R.S., AND WILLIAM LOW.

Early in 1887 the authors communicated to the Royal Society the results of experiments made by subjecting iron to strong magnetic force by placing the sample, in the form of a bobbin with a short narrow neck and conical ends, between the pole-pieces of an electromagnet. The experiments have been continued and extended by using much stronger magnetic forces and by testing samples of nickel, cobalt, and various steels, as well as wrought iron and cast iron. The large magnet of the Edinburgh University Laboratory, kindly lent by Prof. Tait, was used throughout the experiments, and allowed the authors to effect a high concentration of the magnetic force by using bobbins the necks of which had a cross-sectional area of (in some cases) only $\frac{1}{1500}$ of the cross-sectional area of the magnet cores. By this means the induction $\mathfrak{B}$ was raised to the following extreme values:—

In wrought iron	45,350 c.g.s.
„ cast iron	31,760 „
„ Bessemer steel	39,880 „
„ Vickers' tool steel	35,820 „
„ Hadfield's manganese steel	14,790 „
„ nickel	21,070 „
„ cobalt	30,210 „

The induction was measured by means of a coil consisting of a single layer of very fine wire wound upon the central neck of the bobbin. Outside of this coil, at a definite distance from it, a second coil was wound, and the magnetic force was determined in the annular space between the two. In a Paper communicated to the Manchester meeting of the British Association, the authors showed that if the force so measured could be proved to have the same value as the magnetic force within the metal neck itself, it would follow that the intensity of magnetism $\mathfrak{J}$ had begun to diminish under the action of excessively strong fields, in the manner which Maxwell's extension of the Weber-Ampère theory of molecular magnets anticipates. In the present Paper the authors discuss at some length the question of how far the magnetic force within the metal is fairly measurable by the magnetic force in the ring of surrounding air, and they show that with the form of cones originally used the force within the metal must have been less than the force outside, by an amount probably sufficient to explain the apparent decrease of $\mathfrak{J}$. The form of cone suited to give a uniform field of force with sensibly the same value in the metal neck and round it is investigated; and experiments are described in which the condition necessary for a uniform field was satisfied. The results of these experiments are conclusive in showing that no considerable change takes place in the value of $\mathfrak{J}$ (in wrought iron) when the magnetic force is varied from about 2,000 to 20,000 C.-G.-S. units. Throughout this range of force the intensity of magnetism has a sensibly constant value of about 1,700 C.-G.-S. units, which is to be accepted as the saturation value for wrought iron. The term saturation may be properly applied in speaking of the intensity of magnetism, but there appears to be no limit to the degree to which the magnetic induction may be raised.

To produce the greatest concentration of force upon the central neck, the converging pole faces should have the form of cones, with a common vertex in the middle of the neck, and with a semi-vertical angle of 54° 44′. This form, however, does not give a uniform field in the neighbourhood of the vertex. To secure that, the condition is that d^2F/dx^2, d^2F/dy^2, and d^2F/dz^2 shall vanish, F being the magnetic force at the vertex, which is due mainly to the free magnetism distributed over the pole faces. The condition for a uniform field is satisfied when the cones have a semi-vertical angle of 39° 14′. When this form is given to the cones, the magnetic force in the air immediately surrounding the central neck may be taken as sensibly equal to the force within the neck, and it therefore becomes practicable to measure the relation of the induction to the force producing it, that is to say, the magnetic permeability.

The greatest attainable concentration may be calculated by assuming the pole faces to be saturated, when the cones are such as to have maximum concentrative power (semi-vertical angle = 54° 44′). Under these circumstances the magnetic force at the vertex due to the free magnetism on the conical faces is—

$$18{,}930 \log_{10} \frac{b}{a},$$

where *b* is the diameter of the poles at the base of the cones, and *a* the diameter of the central neck.

The following are probable values of the intensity of magnetism when saturation is reached in the particular metals examined:—

	Saturation value of $\mathfrak{J}$.
Wrought-iron	1,700
Cast-iron	1,240
Nickel (with 0·75 per cent. of iron)	515
Nickel (with 0·56 per cent. of iron)	400
Cobalt (with 1·66 per cent. of iron)	1,300

Experiments were also made with specimens of Vickers' tool steel, and other crucible steels, Whitworth's fluid-compressed steel, Bessemer steel, Siemens steel, and Hadfield's manganese steel. This last material, which is noted for its extraordinary impermeability to magnetic induction, was found to have a constant permeability of about 1·4 throughout the range of forces applied to it—namely, from 2,000 to nearly 10,000 C.-G.-S.

The results are exhibited graphically by curves drawn in Rowland's manner to show the relation of the permeability to the magnetic induction. In the highest field examined the permeability of wrought-iron had fallen to about 2.

* Abstract of a Paper read before the Royal Society, Thursday, 22nd November, 1888.

AN ELECTRIC CRANE BY MESSRS. CROMPTON AND CO.

At Messrs. Herrmann and Co.'s wood-working factory in Dod-street, Limehouse, there is now in use a portable and self-propelling crane, driven by an electric motor. The premises, which are of an extensive character, are lit with about 300 incandescent lamps from a Crompton 18-unit dynamo, giving 110 volts. This machine also supplies the current by which the crane is worked. The crane is used for unloading timber from barges lying in the canal at the back of the building, and is required to transfer the load to any one of the several rooms on each floor of the warehouse. For this purpose the crane is mounted upon the flat roof of the building, where it runs on rails, which also traverse a wooden staging projecting over the canal. There is a sharp curve in one part of the track.

The specification required that the motor should lift 15cwt. as a maximum load, and should raise 10cwt. at the rate of 80ft. a minute, that it should travel on the track at the rate of 80ft. per minute, and should slew at about the same speed. It was further specified that, if required, any two of these motions should be performed at the same time; but it was not required to hoist, travel

Digitized by Google

and slew all at once. As a matter of fact, the plant supplied by Messrs. Crompton has exceeded the requirements of the specification in every particular. The motor is capable of lifting several hundredweight in excess, it does its work more rapidly, and is able to undertake all three operations at the same time. For hoisting the full load a current of 50 amperes is required, for travelling and slewing 35 amperes, and for the travelling alone from 23 to 35 amperes, the E.M.F. being constant at 110 volts. The motor is shunt-wound, and runs at a constant speed of 835 revolutions. A few turns of wire are wound outside the magnets, and at starting this is placed in series with the armature, and has the double advantage of checking the excess of current and of ensuring the excitation of the field. These coils are switched out of circuit as soon as the normal speed is attained. The mechanical devices are controlled by three levers and one footbrake, which are all easily controlled by the driver. The direction of running is never reversed, the reversals being effected by means of clutches, as shown in Figs. 1 and 2, which represent the gearing in plan and elevation. The motor drives the whole of the movements through a friction gearing of the Raworth type.

In carrying out the design and construction of this crane, Messrs. Crompton have been ably assisted by Mr. Hollick, acting on behalf of Messrs. Herrmann. After the crane was completed and erected, many points of detail in construction were found to require slight modifications or strengthening, and on all these points Mr. Hass, who is Mr. Herrmann's representative, gave further able assistance. The result has, in the end, been eminently satisfactory. Not only has the specification been completely accomplished, but, as we have already mentioned, the requirements therein set forth have been considerably exceeded. The crane has now been in constant use for nearly two months, and Mr. Hass informs us that it has worked to his entire satisfaction. We understand that the sole reason why an electric crane was thought of was the fact that the

insurance offices declined to renew the policy if a steam travelling crane was placed in the position required. The arrangement of gear on this crane would be readily applicable to derrick cranes and other kinds of hoisting gear, travellers, &c., and it is obvious that there is a great saving of wear and tear, as compared with the ordinary portable steam cranes. We confidently look for a considerable extension of electrical engineering in the direction indicated.

THE SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

On Thursday, the 22nd inst., the meeting of this society was held in the Theatre of the Institution of Civil Engineers, Westminster, the President (Mr. Graves) in the chair.

The SECRETARY (Mr. Webb) having read the minutes of the last meeting,

The PRESIDENT announced that, owing to some formalities in connection with the Joint Stock Companies Act, the name of their society could not be changed to the Institute of Electrical Engineers until January next. He then called upon

Mr. HENRY EDMUNDS, M.S.T.E., to read his Paper on

"A System of Electrical Distribution."

[*The Paper appeared in the last number of The Electrician.*]*

After the reading of the paper, the discussion was opened by

Mr. RECKENZAUN, who congratulated the author on the ingenious manner in which he had carried out his problem. He had the privilege of seeing the apparatus at work a few weeks ago at Mr. Edmunds' place at Hatton-garden, and he was very much surprised at its accurate working. The only objection to the apparatus was that it appeared to be too delicate when placed in a station where the accumulators might be in proximity to the apparatus, for there was a possibility of the fumes causing the metal to get tarnished. He was very much surprised to find that the sparking was almost invisible even with a current of 70 amperes. He believed it would be difficult to charge at 2·25, because the counter electro-motive force of the battery was practically that, and sometimes a little more, owing to the hydrogen gas which was nearly always on the surface of the plates, and generally produced a fictitious electro-motive force, which was frequently above 2·25 volts.

Mr. PREECE said there was something remarkably enticing in this system. Broadly, the principle had about it the merit not only of novelty but of access, and it also had been worked out in a manner that reflected the very highest credit on Mr. Edmunds. He thought, however, that it was still in the experimental stage, where it was laden rather with excrescences, that would have in practice to be cut off. Mr. Edmunds deserved a considerable amount of thanks for bringing a new thing before them in order that they might think it out for themselves. He attributed the absence of sparks to the absence of self-induction in the circuit. He should like to have some further explanation from Mr. Edmunds as to the means by which, without a governor, without a compound winding, without any contrivance of any kind, he succeeded in maintaining a constant current in his circuit. Mr. Edmunds said it was so, and he supposed they were bound to believe it; but there was something peculiar about it, and something that required examination. As to the automatic switch, he must say, as a practical man, that he disliked the introduction of any complicated apparatus to add to the complication of an already complicated system, and that the process should be simplified as much as possible. He could not help thinking a misconception existed about the behaviour of batteries when charged and when discharged. The curve showing the rise of voltage hour by hour as the battery was charged was a curve perfectly familiar to him; but there was another curve wanted, and that was the curve of current. If they took a record of the variation of voltage during the time a battery was charged, and also a variation of current, they would find that while the voltage was increasing the current was diminishing. When they discharged they discharged a battery at a very much lower voltage, and the general impression of the great majority of men in that room was that under these circumstances they got a great loss of energy. Well, they did not. As a matter of fact a secondary battery had one remarkable point connected with it that had raised very little attention, and it was this, that a battery was a kind of automatic governor, that the internal resistance of the battery varied with the current that went through it, so that if they discharged a battery at one ampere they got one resistance, and if they discharged at ten amperes they got very nearly one-tenth of the internal resistance. The result was although unquestionably the voltage of discharge was very much lower than the voltage of charge, the number of watts in a given time was practically the same; so that if they put, say, 300 amperes into a battery, they could, when they discharged it with a small current, get nearly the whole of their energy out of it. He had succeeded in extracting from a battery 98 per cent. of the energy put in, and that was due to the fact that the internal resistance varied with the current of discharge (applause).

* A detailed account of the working of the "distributor," which is not given in Mr. Edmunds' paper, will be found on page 110 of the present issue.

Mr. W. L. MADGEN: I do not wish to say anything tending to revive the discussion between the adherents of the alternating and battery transformer systems, as both parties seem to have buried the hatchet, determined to work their respective methods, and leave time to show which is best; but a marked change has taken place in the aspect of the battery transformer system since the discussions on Mr. Crompton's and Mr. Kapp's papers. It was then implied that as the function of the cells would be principally that of "potential reducers," the entire loss by conversion would not be incurred. But that position has now been abandoned, and I understand it to have been made a rule that house-circuits are not to be connected with the battery at the same time as the primary or high-tension main. Mr. Edmunds seemed to justify the use of house-conductors of a lower grade insulation with his system than are now being generally used in connection with the alternating current service, but I do not suppose that the extra price for equally well insulated conductors will make very much difference, and the tendency to use less reliable is, at least, one which should not be encouraged.

Mr. D. C. BATE said it seemed not only would this system of secondary battery distribution not reduce but it was liable actually to increase the cost, not only over transformer systems but also over other battery systems. Here, if the batteries were discharged at more than an average amount of one-third of the maximum charging current, they would have a direct loss. Taking 70 amperes as being put in, the battery must not discharge more than 23 amperes, or there would be a considerable reduction instead of an increase. That necessitated very much larger cells than if, as was done on the Colchester system, the batteries were allowed to discharge at their full rate, and then replaced by others of an equal capacity. The solenoid to cut-out batteries by reversal of the dynamo current appeared an unnecessary complication if the station was intended to run for 24 hours. He did not understand Mr. Edmunds' engine running without a governor, and he hoped that he would be able to give them some more information on that point.

Mr. KAPP said Mr. Preece had spoken about the system of working the steam engine without a governor as if it were something doubtful or dangerous. Well, Mr. Berenstein had done it years ago, and there was nothing doubtful about it at all. It was a method of working based upon the well-known fact that, with a constant field and constant torque (the steam pressure on the piston being constant), the current must also be constant. On this account the engine adopted by Mr. Edmunds would give no trouble; but he thought that it would give trouble in another way, viz., in the coal bill. Engines were very patient things. They might work them up to different degrees of expansion and different speeds and they would consume the same amount of steam per horse-power; but there was a limit to their patience, and if they worked an engine just crawling around, the weight of water per horse-power would considerably increase. The reason was that the steam had time at each stroke to condense in the cylinder. The great advantage of high-speed engines was that the steam had no time to condense. The cylinder, although it might be of a metal which conducted heat very quickly, would not have time to take away many heat units. Working the engine in that way was almost as good as if the cylinder was made of a non-conducting material. Running an engine slowly was a comfortable thing for the man in charge, but it was not good for the man who had to pay the coal bill. It was therefore a questionable advantage to work in this manner, although the working was perfectly possible on scientific grounds. He should like to put a question to Mr. Edmunds. That gentleman had said that his generating plant, boilers, engines and dynamo need only be one-third the size of what would be required in a battery system arranged on what was generally known as the Colchester plan—two batteries, one charging whilst the other was working the local circuit. On first looking at it it seemed right, but he was not quite sure that it was so. One of the conditions of working these batteries was that they should only receive small increments of charge for two minutes, and during the next six minutes discharge these, in order that there should be no accumulation of charge which would raise the electromotive force beyond the middle part of the curve. If that was so, he could not see how Mr. Edmunds saved anything over a direct supply system. If, on the other hand, they allowed the cells to accumulate a charge, then the argument fell to the ground that the batteries were used in a better way than usually; and, in fact, the circumstance that Mr. Edmunds put a regulating magnet which came into action upon a rise of potential, showed that he anticipated the batteries would accumulate a charge and oppose a greater electromotive force than 2·2 volts. Could this magnet be so delicately adjusted as to come into play with, say, 2·25 volts? If that was so he could understand that the lamps could be worked to a higher voltage than that labelled, and the light would be exceedingly steady. But then they were on the other horn of the dilemma, namely, during the daytime the engines would work very much under power. They lived, as in an ordinary direct supply system so to speak, from hand to mouth, for the consumer would take in the evening as much as the engine could produce. He should like to draw attention to the very beautiful electro-magnet used by Mr. Edmunds in his voltage regulator. He thought he had seen it elsewhere before, but, at any rate, the device was worthy of their consideration. In this magnet Mr. Edmunds had got over what Mr. Preece had called "the pest" of magneto-electric apparatus, viz., self-induction. They had one circuit always closed, and therefore in that circuit there was no sparking, and in the other circuit of high resistance there was also no sparking when the contact was opened. When the shunt current flowed the core was not magnetised, and therefore on breaking it the spark was only that due to the small current flowing through an inert resistance. On closing when the core was magnetised they could, of course, not have any sparking, so that really in this case they had an electro-magnetic instrument which might be put in and out of action and giving all the advantages of the magnet, and yet without its disadvantages of self-induction. He was rather sorry that the motor generator had got into the diagram. They did not care to have

Digitized by Google

machinery in a house, not even in a theatre if they could help it, and he hoped that such a generator would not be used. One of the advantages of Mr. Edmunds' system was that he could have perfect insulation. With a motor generator they could not get this insulation.

Mr. A. P. TROTTER said he could quite corroborate what Mr. Kapp had said about the constant current. He remembered some time ago taking great pains to make an accurate constant-current regulator, and found that it was much better to throw off the governor and to let the engine go ahead. To what extent that could be done on a large scale he was not able to say. It was an extremely ingenious system, but they would like to look at the figures. Great stress had been laid upon the insulation and that the main was quite apart from the batteries, but as he understood the matter six thousand volts went fooling around that beautiful arrangement (laughter). Still, he should like to know in inches the actual thickness of insulation. The main, he apprehended, got inside the box with the other contacts (laughter). He did not like to be flippant about the thing, for he could not but admire the extreme ingenuity which Mr. Edmunds had displayed.

Professor FORBES said they were all agreed that the subject which had been introduced to them was one which was absorbing attention more now than it had done, and was also one upon which they were looking to such fertile inventors as Mr. Edmunds to give them new materials in the future. Having now become thoroughly satisfied with the satisfactory performance of one system of distribution, they naturally looked forward to the time when they should be able to distribute on an alternative plan. The chief difference which he noticed in a general principle between Mr. Edmunds' system and other systems which had been proposed for using secondary batteries was in this ingenious plan of charging and discharging cells alternately at short intervals of time. In other systems of using accumulators trouble arose from the fact that when they put the fully charged cells into the circuit they had a higher voltage for a short time, and one or two cells had to be cut out. The complicated devices which had been attempted to be used to accomplish this end had, so far as he had seen them at present, not been successful. There were some, he believed, which had lately been brought out, but which he had not yet investigated. But Mr. Edmunds's seemed to be the first one free from that difficulty. It seemed to him that in this system batteries were never used at a higher charge than half their charge, and it also appeared that they were depending upon the capacity of the battery, and therefore they were depending with those batteries upon only half the charge that they were really capable of using. He knew that when that was put by some other speaker, Mr. Edmunds made some expression of dissent, but he (Prof. Forbes) failed to see his way out of the difficulty, and he should be glad to hear Mr. Edmunds' answer to that. Incidentally he was extremely pleased to hear Mr. Edmunds responsible for a statement that he had lamps which were working with two and a-half watts per candle-power, and whose light was considerably over one thousand hours. This was news to him, and he should be glad to know something more about the lamps. When Mr. Edmunds was describing his regulating arrangement, it occurred to him that this was exactly the converse of the result in motor work which was first announced by M. Deprez, that was to say, when they had a series motor or a motor excited by a constant current, they might vary the load as much as they pleased and the volts would go up, but the current would remain perfectly constant as long as the pressure remained so. Now that was the converse thing as applied to the dynamo. That was the case of a dynamo working against a constant pressure, and this was the case of a dynamo being driven by a constant pressure from the steam engine. He should like fuller details about the method of introducing a second and third engine to assist the work. It seemed that Mr. Edmunds had passed it over a little lightly, and that it was not quite such a simple affair as he would lead them to believe. The weakest point, as it seemed to him, in the necessary apparatus in the system was in that make and break which Mr. Kapp had approved of so much. It appeared to him (the Professor) that in an apparatus which had to be constantly at work day and night without attention in the consumer's house, that anything in the shape of a make and break was to be condemned at once. In conclusion, he thought the first general feeling they had about this system was that there was a little too much complexity in the apparatus which had to be put into every individual house, and it would have been well if Mr. Edmunds could have given them some approximate notion of the cost of this apparatus, which had to be added to all the ordinary apparatus with which a house was installed. If he had been a little critical it was not his intention. He was extremely delighted with the general scheme put before them; and he was certain that every one would be looking forward to the development of Mr. Edmunds' system, and seeing how it actually worked out in commercial practice.

Mr. EDMUNDS said he had a great many questions to answer, and he should like to reply to them at their next meeting.

The CHAIRMAN presumed that there would be no objection to Mr. Edmunds doing so, and at their next meeting, on the 13th December, Mr. Edmunds could reply to the whole of the observations.

The discussion was then adjourned.

Exports of Telegraphic Wires and Apparatus connected therewith.—Our exports of telegraphic wire and apparatus connected therewith continue to show a most unsatisfactory falling off. The following are comparative figures for October, and for the ten months ended October 31, taken from the Board of Trade returns issued this week :—

Exports.	1888.	1887.	1886.
October	£17,038	£31,475	£60,467
Jan. 1 to Oct. 31	£414,177	£688,539	£951,088

THE ELECTRICIANS' DIRECTORY AND HANDBOOK FOR 1889.

The 1889 edition of this well-known DIRECTORY and HANDBOOK, which claims to be the best and most reliable international medium of intercommunication devoted to the electrical and allied trades (containing, as it does, a large number of useful statistics and tables of considerable interest to those engaged in electrical pursuits all over the world) is nearly ready for press. The Publisher notifies that the time for receiving new names, addresses, corrections, and advertisements will shortly expire, and that firms and individuals requiring their names inserted in the book should send at once.

The price of the Directory, when ready, will be Four Shillings, prepaid.

All further particulars will be forwarded by the Publisher upon receipt of inquiry.

BOOKS, &c., RECEIVED.

"Traité de Télégraphie Sous-Marine." By E. WÜNSCHENDORFF. (Paris : Baudry et Cie.)

"Étude Théorique des Transformateurs." (Extracted from *l'Electricien.*) By CHARLES JACQUIN. (Paris : G. Masson.)

"Technology Quarterly." Vol. II. No. 1. (Boston).

"The Daft System of Electrical Railway Propulsion." (New York.)

Gent and Co.'s "Illustrated List of Galvanic and Other Instruments used in the Practice of Electro-Therapeutics."

"Die Erzeugung und Verteilung der Elektrizität in Zentral Stationen." By Dr. MARTIN KRIEG. Vol. II. (Magdeburg: A. and R. Faber.)

"Die Accumulatoren für Elektricität." By EDMUND HOPPE. (Berlin : Julius Springer.)

"Kalender für Elektrotechniker." By F. UPPENBORN. (Munich and Leipzig : R. Oldenbourg, 1889.)

MEETINGS OF SCIENTIFIC SOCIETIES, &c.

(To-night) FRIDAY, November 30th.

INSTITUTION OF CIVIL ENGINEERS.

7:30 p.m. Students' Meeting. "The Covered Service-Reservoir of the Southampton Corporation." By E. T. HILDRED, Stud. Inst. C.E. "On the New High-Level Storage Reservoir for the Grand Junction Waterworks Company at Hanger Hill, Ealing." By H. ASHLEY, Stud. Inst. C.E.

ELECTRO-HARMONIC SOCIETY.

8 p.m. Amateur Concert. Ladies' night. St. James's Hall Restaurant.

MONDAY, December 3rd.

SOCIETY OF ENGINEERS.

7:30 p.m. A Paper will be read at the Westminster Town Hall on "High Pressure Steam and Steam Engine Efficiency." By Mr. W. WORBY BEAUMONT, M.I.C.E.

SOCIETY OF ARTS.

8 p.m. Cantor Lecture. "Light and Colour." Capt. W. de W. ABNEY, C.B., F.R.S. (Second Lecture.)

TUESDAY, December 4th.

INSTITUTION OF CIVIL ENGINEERS.

8 p.m. Ordinary Meeting. "The Influence of Chemical Composition on the Strength of Bessemer Steel Tyres." By Mr. J. OLIVER ARNOLD, F.C.S. At this meeting the first ballot of the session will be taken.

ROYAL VICTORIA HALL.

8 p.m. Lecture, "Nature's Hot Springs." By Mr. S. RIDEAL.

WEDNESDAY, December 5th.

CITY AND GUILDS OLD STUDENTS' ASSOCIATION.

7:45 p.m. General Meeting at the Central Institution, Exhibition-road. A Paper will be read on "Aluminium," by Mr. W. M. HELLER.

SOCIETY OF ARTS.

8 p.m. Ordinary Meeting. "The Graphophone." By Mr. HENRY EDMUNDS.

THURSDAY, December 6th.

SOCIETY OF TELEGRAPH ENGINEERS.

8 p.m. Students' Meeting. "Electric Light Measurements." By Messrs. A. H. BATE and GIMINGHAM.

SATURDAY, December 8th.

PHYSICAL SOCIETY.

3 p.m. "On Some Facts Connected with Systems of Scientific Units of Measurements." By Mr. T. H. BLAKESLEY.

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny.
Editorial, Publishing and Printing Offices:

No. 1, SALISBURY COURT, FLEET STREET, LONDON, E.C.

Telephone No. 2714.

All Communications to be addressed to "The Electrician," 1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to "The Electrician."

All letters intended for insertion in "The Electrician," or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.

"The Electrician" is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.

"The Electrician" is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.

SPECIAL NOTICE.

Owing to the increase in the number of pages of "The Electrician," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.	6 months.	12 months.
For Foreign Parts and Colonies:—	s. d.	s. d.	s. d.
Within Postal Union	6 6	12 6	24 0
„ Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	14 6	28 0
The rates for the United Kingdom remain as follows:—	5 0	10 0	19 6

TO ADVERTISERS.

"The Electrician" offers exceptional advantages to Advertisers. **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

Trade Advertisements *intended for the current issue must be handed in not later than First Post on Thursday morning.*

Small Prepaid Advertisements *(for Rates see page xi.) are accepted up to 4:30 p.m. on Thursday.*

TECHNICAL PRINTING.

"The Electrician" Printing and Publishing Company (Limited) *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

The Electricians' Directory.

Royal 8vo. Cloth Boards, 3s. 6d., post free 4s.

At the commencement of each year is issued The Electricians' Directory and Handbook. *The Directory was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

THE DIRECTORY FOR 1889 IS IN PREPARATION,

And new names and addresses are now being received.

THE PACIFIC CABLE CONFERENCE.

The Pacific Telegraph Cable scheme depends on so many improbable contingencies that at first sight it seems hardly worth while to treat the project seriously. First of all, the Pacific Ocean has not yet been explored, or explored only with the result of demonstrating how hazardous would be any cable-laying operations on a large scale in those waters. Next, a very heavy subsidy from the British, Canadian and Australasian Governments has to be obtained. And, lastly, with these adverse conditions yet unsatisfied, the financial public will have to be induced to subscribe—or promise to subscribe—the necessary funds to defray the cost of an undertaking of which the success is extremely problematical, and the commercial failure almost certain. Nevertheless, there were some features of the conference held last week to discuss this subject deserving the attention of those who are well-wishers of cable-laying enterprise, one of which was the perfect candour of the noble lord who presided, and who, to the best of his ability, explained the objects of the meeting. They were assembled, said Lord Winchilsea, simply as men of business to set forward their own interests as traders; and he intimated pretty plainly that

Digitized by Google

nobody else's interests would receive much consideration at their hands. They had to consider only whether the existing means of communication with the Australasian colonies were sufficient, whether they were safe, and whether they were as cheap as they ought to be.

Now, had these propositions been placed before a conference of experts, or of men with any recognised standing in the business of submarine telegraphy, the worthy chairman would have been promptly reminded that several other conditions vital to the problem under discussion would require a strict examination—such, for example, as whether a cheap rate could be made remunerative; whether a deep-sea cable is any safer for being out of reach; and whether, with existing cables not fully employed, their insufficiency is proved by there being room for another on a different route. But, unfortunately, at the Cannon-street Hotel conference the audience, so far as we can gather, were not of that character; and, judging by the language of those who took part in the speech-making, were chiefly colonialists, or customers of the present cable companies anxious to see the Australian and New Zealand rates cheapened, but not at all mindful of how it is to be done, or of who bears the risk, so long as the scheme offers some promise of lessening their business expenses.

Of course there was the usual talk about forging another link in the chain which binds the mother country to her colonies; but talk of that description, however commendable it may be, has never yet caused a cable to be laid, and never will, except when there is a proved necessity for it. The proofs adduced in this instance are far from being convincing. By some untoward accident both the two Australasian cables have been rather seriously interrupted of late; but they were promptly repaired, and their past history shows as good a record of stability as any cables that have ever been laid. Besides this, a third cable is about to be submerged, affording an additional link which is not likely to be broken simultaneously with the other two. The chain has been forged link by link until it has reached this furthermost colony of the Empire; and the choice of route has been more a matter of geographical and commercial necessity than of calculation. But until now the Pacific has been avoided for practical reasons sufficiently cogent. Its depth is enormous, and its bottom is known to be traversed by ridges which would render the life of a cable bridging the intervals exceedingly insecure. An experiment of that kind, although profoundly interesting, would be attended with great risks, and as nothing was to be gained by it, none of the established cable companies have thought it expedient to extend operations in that direction. Judged, therefore, by practical and prudential considerations, the project for connecting Australia with England through Vancouver and Canada, by way of the Pacific, is not an attractive one. But as the public are invited to support it on other and higher grounds, we will do our best to examine them and see what they amount to.

Reduced to their true dimensions the arguments for this Pacific route are chiefly these, namely, that the construction of the Canadian Pacific line of railway and telegraph has rendered that route of great imperial importance, requiring it to be supplemented and completed by a connecting cable between its western extremity and the Australian colonies; and, secondly, that this cable being in very deep water, would be safe from the depredation of any hostile cruiser. As regards the first of these propositions, we may observe that the Canadian Pacific Railroad would be useful to us, if useful at all, to convey troops for India rather than to Australia; and is, moreover, flanked the whole distance by the foreign, and possibly unfriendly, territory of the United States—a fact which it is fair to point out, seeing that the advocates of the Pacific route object to the Eastern route because it passes over, or is in close proximity to, foreign territories. One gentleman went so far as to recommend the new scheme because "it would go across British territory entirely"—his idea seeming to be that Britannia not only rules the waves but owns all beneath them. We do not by any means undervalue the argument for independent routes; but its importance may easily be exaggerated. It ought not to be assumed that every foreign country is going to be an enemy; on the contrary, it might in many cases be argued, with just as much reason, that a foreign section will be inviolate because of its being on friendly soil. As a fact, however, the routes to the far East, as an examination of any telegraph map will show, is remarkably independent of foreign guardianship; and except for the hazards of naval warfare is practically unassailable.

This brings us to the point on which the Pacific cable promotors think themselves strongest. In case of war it would be extremely difficult, so it is alleged, to destroy the cable. Passing over the suicidal character of this contention, which condemns the cable to permanent loss if accidently broken, we may remark that the continuity of this or any other cable can be effectively destroyed without molesting its deepest portions. Why should an enemy's cruiser try to drag up a cable from the bottom of the Pacific when the object could be accomplished in shallow waters? And it happens that the intervening points of landing in the case of the projected Pacific cable would be singularly exposed to an attack of that kind; whereas the Eastern and Eastern Extension cables enjoy the advantage of being laid along routes most frequented by ships carrying the British flag. The simple fact is that all submarine cables belonging to belligerents will be remorselessly destroyed wherever they can be got at; and the only way in which English cables may escape interruption on the outbreak of hostilities is to lay them where English men-of-war are most likely to afford them protection. Obviously this kind of protection, such as it is, would cover a Pacific cable hardly at all; and unless some more urgent reasons of State for its construction can be adduced than those put forward at last week's conference, we suspect that neither the British Government nor the British public will lend any substantial assistance to the scheme.

OBITUARY.

M. LUCIEN GAULARD.

The death of M. Lucien Gaulard took place in Paris on Monday, the 26th inst. M. Gaulard was born in 1850, and was well-known in French and English scientific circles. His name is associated principally with the system of electrical distribution by secondary generators, which occupied his sole attention during the last six or seven years; his earlier efforts were devoted to various branches of electrical and chemical science. In 1881 M. Gaulard showed at the Electrical Exhibition in Paris his thermo-electric battery, which excited a great deal of attention. It was at this time that M. Gaulard was invited by Mr. Gibbs to come to London, and since then, up to the time of M. Gaulard's illness in the spring of the present year, he was a director of the National Company for the Distribution of Electricity by Secondary Generators (Limited). M. Gaulard was a member of the Society of Telegraph-Engineers, and was decorated by the King of Italy at the Turin Exhibition in 1884. He leaves a widow but no family.

The history of invention scarcely contains a more mournful story than that of M. Gaulard. To him, beyond all question, belongs the honour of having initiated one of the most brilliant and successful developments of electrical engineering. The fact that the idea itself already lay dormant in the records of

Digitized by Google

the Patent Office cannot in the least detract from the merit of the man who first realised its value, and who, in spite of all difficulty, and in spite, it must be said, of the serious deficiencies of the particular method by which he sought to carry out his projects, forced the electrical world to recognise the immense importance of the alternate-current transformer. By a most unhappy fate, M. Gaulard contrived just to miss the one point of detail in the method of using his apparatus which involved the difference between commercial success and practical failure. Having thus missed his way, he had, in consequence, to suffer the mortification of standing idly by whilst other men were eagerly pursuing the track upon which he first set out. But though it is impossible not to feel the deepest sympathy for the unfortunate position in which M. Gaulard was placed, we believe it to be equally impossible to cast the blame of his misfortunes upon other shoulders. In actual life every man must abide the fortune of war with such fortitude as his individual temperament may permit. Unhappily, in this case, the strain proved at length to be greater than the mental equilibrium of the inventor could sustain. And notwithstanding the gleam of sunshine which the purchase of the American patent by the Westinghouse Company must have brought, yet in the early part of last summer his intellect became clouded, and it was found necessary to place him under restraint. His death has taken place just at the moment when the methods which he inaugurated are about to be applied upon a scale of hitherto undreamt of magnitude. In our correspondence columns will be found a letter from M. Cadiot, which expresses the feeling which has been called forth in Paris, and which will be very largely shared by the electricians both of this country and of America.

PHYSICAL SOCIETY.

At a meeting of the Physical Society, held on November 24, 1888, Prof. A. W. Reinold, F.R.S., President, in the chair, a Paper was read on

"The Suppressed Dimensions of Physical Quantities."

BY PROF. A. W. RÜCKER, F.R.S.

The author observed that there was no scientific novelty in what he had to bring before the Society, but he was of opinion that there was room for discussion whether the admitted facts with regard to the dimensions of physical quantities were expressed in the best possible manner by the methods in ordinary use.

In determining the dimensions of physical quantities, it was well known that there was often only a single equation containing two unknown quantities, which made the problem indeterminate. The difficulty was generally got over by assuming one to be a mere number, and then calculating the other. This would do very well if the dimensions were to be used merely for testing the comparability of the terms of a physical equation, but it would not be possible to arrive at a definition of the quantities from their dimensions, as could be done with the simpler physical quantities, such as acceleration, work, power, &c.

In the case of heat, the question arose what were the dimensions of temperature? Consider such an equation as $M L^2 T^{-2} = J M c \theta$, where L, M, T, θ are the units of length, mass, time and temperature, J the mechanical equivalent of heat, and c the specific heat of the substance considered. Taking c as a mere number, and putting it equal to unity, this becomes $[L^2 T^{-2} \theta^{-1}] = [J]$. It was clearly impossible to consider θ as a mere number, since the value of J depended on the units in which θ was measured, though on the other hand temperature, as measured on the ordinary thermometric scales, was indedendent of the units of time, length and mass.

In such a case two courses were open. Either some relation might be assumed to exist between θ and the three fundamental units, and hence the dimensions of θ determined, or it might be kept in the equations as a kind of secondary fundamental unit, necessary for thermal measurements, but not expressible in terms of the fundamental units on account of our ignorance, and the artificial methods by which we measured temperature.

The author observed that if our knowledge of the molecular dynamics of liquids and solids warranted us in extending to them the analogy of gases, temperature might be defined as the mean energy of translation of a molecule, or of a standard number of molecules which would give $M L^2 T^{-2}$ for its dimensions in terms of the fundamental units, and it would be independent of the properties of any special substance. It might be possible that when our knowledge became more extended some system of this kind might be adopted for the measurement of temperature.

Taking the temperature θ as a secondary fundamental unit, assuming the specific heat to be a mere number, and assuming the unit of heat to be defined with reference to the unit mass of water, the author obtains the following table of dimensions of thermal quantities :—

Name of Quantity.	Dimensions of Unit.
Quantity of heat	$[M\theta]$
Mechanical equivalent of heat	$[L^2 T^{-2} \theta^{-1}]$
Specific heat	0
Latent heat	$[\theta]$
Thermal capacity	$[M]$
Coefficient of expansion	$[\theta^{-1}]$
Coefficients of absorption and emission	$[M L^{-2} T^{-1}]$
Coefficient of conductivity	$[M L^{-1} T^{-1}]$
Entropy	$[M]$

The author then indicated a method of treating gravitational units, and pointed out that a distinction had to be made between the nominal unit of mass in such a system M and the real unit $M\gamma$, where γ was the numerical quantity expressing the acceleration of gravity in terms of the units of length and time employed. In such a system the three fundamental units were really length, time, and force, mass being a derived unit, M, subject to the condition that $\gamma L T^{-2}$ should represent a given concrete acceleration.

The cases of practical importance were force, work, power, and the mechanical equivalent of heat, and if the numerical measure of any of these quantities were multiplied by the numerical quantity γ transformations could be effected as usual by aid of the condition $\gamma L T^{-2} =$ constant.

Thus, if J_1 J'_γ and J''_γ were the numerical values of the mechanical equivalent of heat in an absolute, and two gravitational systems respectively

$$J [L^2 T^{-2} \theta^{-1}] = J'_\gamma \gamma' [L'^2 T'^{-2} \theta'^{-1}] = J''_\gamma \gamma'' [L''^2 T''^{-2} \theta''^{-1}],$$

or, if n n' were the numerical values of a power in an absolute and a gravitational system respectively,

$$n [M L^2 T^{-3}] = n' \gamma [M' L'^2 T'^{-3}].$$

The author pointed out that J was only independent of the unit of mass when the unit of force and the unit of heat were defined with respect to the same unit of mass, and it did not, therefore, hold good in the English system, where the unit of heat was defined with reference to the pound, while the force being measured in gravitational units was defined with reference to a mass of 32·2 pounds.

In the case of electrical and magnetic measurements the author pointed out that the question was one of much greater practical importance than in the case of thermal measurements. Maxwell had shown that the number of independent relations between electrical and magnetic units was one less than the number required to determine them completely.

The two systems in use, namely, the electrostatic and the electromagnetic, were founded on two different assumptions, which amounted to the suppression of the dimensions of specific inductive capacity and magnetic permeability respectively, and it was these suppressions which led to the differences, so perplexing to students, in the dimensions of electrical and magnetic quantities expressed in the two systems. The author, therefore, suggested the advisability of retaining symbols representing these quantities as secondary fundamental units in the tables of dimensions. If this were done the cause of the difference in dimensions would be brought prominently forward, and the factors required to transform from one system to the other would be clearly indicated.

If the proposed system were adopted, we should have, using Maxwell's notation,

$$[\mathfrak{D}] = [K \mathfrak{E}],$$
$$[\mathfrak{D}\,\mathfrak{E}] = [M L^{-1} T^{-2}],$$

and therefore,

$$[\mathfrak{D}] = \left[M^{\frac{1}{2}} L^{-\frac{1}{2}} T^{-1} K^{\frac{1}{2}}\right],$$
$$[\mathfrak{E}] = \left[M^{\frac{1}{2}} L^{-\frac{1}{2}} T^{-1} K^{-\frac{1}{2}}\right],$$

and, similarly,

$$[\mathfrak{H}] = \left[M^{\frac{1}{2}} L^{-\frac{1}{2}} T^{-1} \mu^{\frac{1}{2}}\right],$$
$$[\mathfrak{B}] = \left[M^{\frac{1}{2}} L^{-\frac{1}{2}} T^{-1} \mu^{-\frac{1}{2}}\right].$$

By means of these relations all the units could be expressed in terms either of M, L, T, K, or of M, L, T, μ, and the dimensions in M, L, T, would be those of the electrostatic and electromagnetic systems respectively. For by Maxwell's equations (7) "Electricity and Magnetism," Vol. II., page 243, 2nd edition,

$$[\mathfrak{D}] = [e L^{-2}].$$

Therefore

$$[e] = \left[M^{\frac{1}{2}} L^{\frac{3}{2}} T^{-1} K^{\frac{1}{2}}\right],$$

and by equation (9)

$$[\mathfrak{B}] = [m L^{-2}].$$

Therefore

$$[m] = \left[M^{\frac{1}{2}} L^{\frac{3}{2}} T^{-1} \mu^{\frac{1}{2}}\right],$$

and from the dimensions of $[e]$ and $[m]$ those of all the other units could be found.

Digitized by Google

Maxwell had given a table in which the dimensions of each of the electrical and magnetic units were expressed in terms of L, M, T, and of either electrical quantity, e, or strength of magnetic pole, m. The author's suggestion merely amounted to choosing K and μ instead of e and m, as the two unknown quantities, in terms of which the units should be expressed, which would make the dimensions in L, M, T, the same as those of the electrostatic and electromagnetic units respectively.

The author suggested that quantities expressed in terms of K and μ respectively should be indicated by the suffixes s and m, when it was necessary to indicate the distinction, as for example, e_s and e_m.

By equating two such expressions for the same quantity, or by using any general relation between any two of the derived quantities, we should obtain a necessary relation between the dimensions of the secondary fundamental units in terms of the fundamental units.

Thus from Maxwell's equations (11) or (12) (*loc. cit.*)

$$[e\,m]=\left[\mathrm{M\,L^2\,T^{-1}}\right].$$

Expressing e in terms of K and m in terms of μ, we should have

$$[e\,m]=\left[\mathrm{M^{\frac{1}{2}}\,L^{\frac{3}{2}}\,T^{-1}\,K^{\frac{1}{2}}}\right]\times\left[\mathrm{M^{\frac{1}{2}}\,L^{\frac{3}{2}}\,T^{-1}}\mu^{\frac{1}{2}}\right]$$
$$=\left[\mathrm{M\,L^2\,T^{-1}}\right];$$

whence
$$\left[\mathrm{K^{\frac{1}{2}}}\mu^{-\frac{1}{2}}\right]=\left[\mathrm{L\,T^{-1}}\right].$$

It was evident that such a relation must exist, for since only one equation was wanting to determine the units completely in terms of L, M, T, it was clear that there could not be two independent methods of expressing them.

The author, after giving a series of examples illustrating the advantages of his system in effecting transformations from one system of units to another, gave the following table showing the dimensions of the various electrical units in terms of L, M, T, K, and L, M, T, μ, respectively. Putting K = 1 gives the ordinary electrostatic dimensions, and putting $\mu = 1$ the dimensions in the ordinary electromagnetic system :—

Name of Quantity.	Symbol.	Dimensions in Terms of L, M, T, and K.	Dimensions in Terms of L, M, T, and μ.
Quantity of electricity	e	$\left[\mathrm{L^{\frac{3}{2}}\,M^{\frac{1}{2}}\,T^{-1}\,K^{\frac{1}{2}}}\right]$	$\left[\mathrm{L^{\frac{1}{2}}\,M^{\frac{1}{2}}}\mu^{-\frac{1}{2}}\right]$
Electrical potential	E	$\left[\mathrm{L^{\frac{1}{2}}\,M^{\frac{1}{2}}\,T^{-1}\,K^{-\frac{1}{2}}}\right]$	$\left[\mathrm{L^{\frac{3}{2}}\,M^{\frac{1}{2}}\,T^{-2}}\mu^{\frac{1}{2}}\right]$
Quantity of magnetism	m	$\left[\mathrm{L^{\frac{1}{2}}\,M^{\frac{1}{2}}\,K^{-\frac{1}{2}}}\right]$	$\left[\mathrm{L^{\frac{3}{2}}\,M^{\frac{1}{2}}\,T^{-1}}\mu^{\frac{1}{2}}\right]$
Electrokinetic momentum of a circuit	p		
Electric current	c	$\left[\mathrm{L^{\frac{3}{2}}\,M^{\frac{1}{2}}\,T^{-2}\,K^{\frac{1}{2}}}\right]$	$\left[\mathrm{L^{\frac{1}{2}}\,M^{\frac{1}{2}}\,T^{-1}}\mu^{-\frac{1}{2}}\right]$
Magnetic potential	Ω

This table he supp'emented by a second containing certain units in which both electrical and thermal quantities occurred. This table, which is given below, was obtained by means of the following relations :—

Thermo-electric height × temperature = E.M.F.
Specific heat of electricity × (temperature)^2 = E.M.F.
Coefficient of Peltier effect × time = heat.

or $\mathrm{J\,\Pi = E.M.F.}$

Name of Quantity.	Symbol.	Dimensions in Terms of L, M, T, θ and K.	Dimensions in Terms of L, M, T, μ and θ.
Thermoelectric Height	ϕ	$\left[\mathrm{L^{\frac{1}{2}}\,M^{\frac{1}{2}}\,T^{-1}\,K^{-\frac{1}{2}}}\theta^{-1}\right]$	$\left[\mathrm{L^{\frac{3}{2}}\,M^{\frac{1}{2}}\,T^{-2}}\mu^{\frac{1}{2}}\theta^{-1}\right]$
Specific Heat of Electricity	k	$\left[\mathrm{L^{\frac{1}{2}}\,M^{\frac{1}{2}}\,T^{-1}\,K^{-\frac{1}{2}}}\theta^{-2}\right]$	$\left[\mathrm{L^{\frac{3}{2}}\,M^{\frac{1}{2}}\,T^{-2}}\mu^{\frac{1}{2}}\theta^{-2}\right]$
Coefficient of Peltier Effect	Π	$\left[\mathrm{L^{-\frac{3}{2}}\,M^{\frac{1}{2}}\,T\,K^{-\frac{1}{2}}}\theta\right]$	$\left[\mathrm{L^{-\frac{1}{2}}\,M^{\frac{1}{2}}}\mu^{\frac{1}{2}}\theta\right]$
Geometrical Capacity	$q'=\frac{q}{\mathrm{K}}$	[L]	[L]

Mr. Blakesley stated that the same difficulty had often occurred to him in connection with the measurement of temperature. He took this opportunity of recording his objection to the term *therm*, which had been recently adopted for the unit of heat. The term was badly derived, for the prefix *therm* was associated with temperature measurements, as, for example, in the words isotherm and thermometer, and not with calorimetric measurements.

Prof. G. C. Foster observed that the subject of the Paper was of great interest and importance, and he hoped that its fuller discussion, after members had had the opportunity of reading Prof. Rücker's Paper in full, would lead to some valuable conclusions.

Prof. S. P. Thompson thought that confusion often occurred from no distinction being drawn between vector and scalar physical quantities. For example, the dimensions of work were given, the same as those of the moment of a force about a point. In the former case, however, a length was multiplied into a length measured in its own direction, while in the latter case a length was multiplied into a length measured at right angles to its direction, and the latter quantity ought therefore to be multiplied by $\sqrt{-1}$.

In connection with this he mentioned a method which he had been accustomed to give to his students of deducing the law that parallel electric currents in the same direction attract each other, from the ordinary law of the inverse square for the repulsion of two magnetic poles. If $m\,m'$ are two similar magnetic poles at a distance r, and the repulsive force f between them be considered positive, we have

$$\frac{m\,m'}{r^2}=f;$$

for the pole m substitute an element of current of corresponding strength, which, as it exerts a force at right angles to its direction, will be represented by $\sqrt{-1}\,ds$, and we have

$$\frac{m\sqrt{-1}\,ds}{r^2}=\sqrt{-1}\,f,$$

and making a similar substitution of $\sqrt{-1}\,ds'$ for m' we have

$$\frac{\sqrt{-1}\,ds\;\sqrt{-1}\,ds'}{r^2}=-f,$$

showing that two parallel currents in the same direction attract each other.

He agreed with Mr. Blakesley in his objection to the term *therm* for the unit of heat, and greatly preferred *calorie*, which had gradually come to be used for the gramme unit of mass instead of the kilogramme, with which it was originally associated.

He stated that ten or twelve years ago Pictet had suggested that temperature might be taken as proportional to the square of the calorific oscillation. He thought it would greatly simplify the idea of specific heat to give up expressing it as a ratio and measure it directly in ergs, since J is merely the specific heat of water in mechanical measure. This would have the effect of eliminating J as a multiplier or divisor in the elementary formulæ of thermodynamics.

Prof. Ayrton observed that the first part of the Paper was of theoretical, and the second part of practical interest. He did not find that students had much difficulty in acquiring accurate ideas of specific heat and temperature, but it was a very different matter in the case of electrical and magnetic quantities.

It was not only students whose ideas of these were confused ; for example, he pointed out that in many standard works, and even in the first report of the British Association Committee on Electrical Units, the velocity v was defined as the ratio of the electrostatic to the electro-magnetic unit of quantity, instead of, as it should be, the reciprocal of this ratio. The misunderstanding arose from a confusion between the units and the numerical measures of the quantities. The simplification of the electrostatic units by the omission of specific inductive capacity was, he thought, most probably due to the fact that Faraday had been under the impression that this constant had the same value for all gases. Boltzmann had shown that this was incorrect, and after the publication of his results the speaker and Prof. Perry had pointed out that the specific inductive capacity of the medium ought to be introduced as a factor into the denominator of the expression for the electrical force between two charged bodies.

Prof. RÜCKER, in reply to Prof. Thompson's remark about the dimensions of work and moment being identical, stated that he had always explained this by considering the moment as measured by a rotation through the unit angle, the dimensions of the latter being admittedly zero. He pointed out that Baynes, in his "Thermo-Dynamics," had eliminated J from the equations by expressing specific heat in ergs; but this was inconvenient, as specific heats in physical tables were not given in ergs, and in preference to advocating such a change at present he would suggest waiting until we had succeeded in obtaining a scientific scale of temperature.

THE EDMUNDS "DISTRIBUTOR."

During the meeting of the Society of Telegraph Engineers and Electricians last week (which is reported on an earlier page of the present issue) Mr. Edmunds exhibited one of his automatic distributors working in connection with some cells which were feeding about twenty incandescent lamps. No charging current being available the changes had to be made by hand. This was done without the slightest perceptible effect upon the lamp. Mr. Edmunds has given no detailed description of the mechanism of the apparatus, which is of a somewhat complex character, but we take the following admirable description from a recent issue of our contemporary, *Engineering*:—

"The motive power is obtained by a magnet, *s* (Fig. 1), while the intervals between the strokes of the armature are measured by

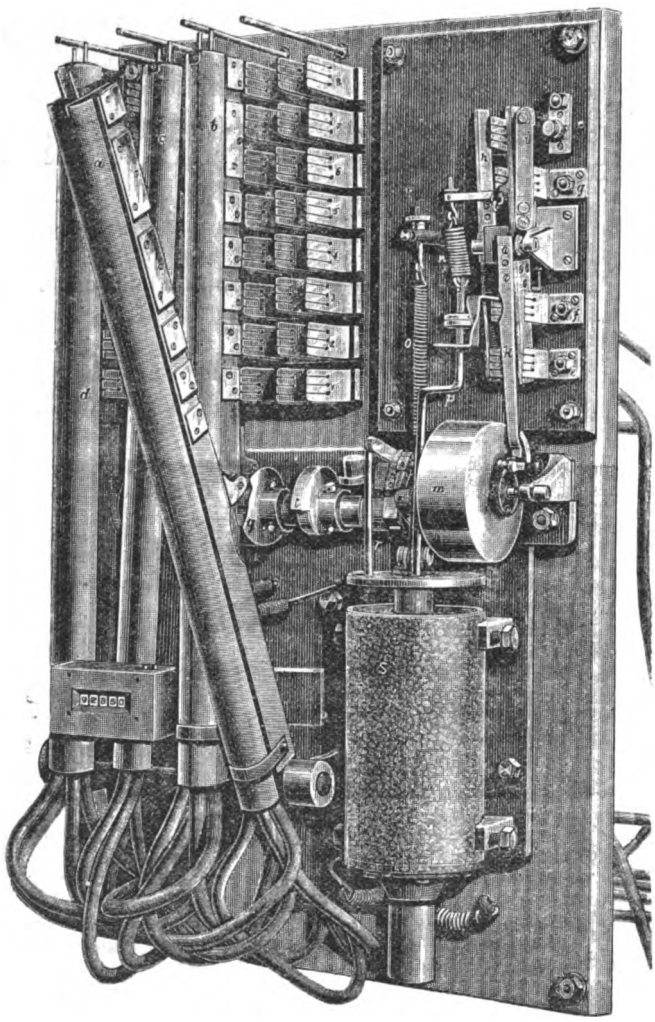

FIG. 1.

the revolving cataract *m* (Figs. 1 and 2). This cataract is a hollow cylinder divided by radial partitions into sections, and partly filled with water. In each section there is a small hole through which the water can leak at a definite speed. On the outside of the cylinder there is a light spiral spring, which is wound up every time the magnet completes a stroke of its armature. This spring then endeavours to rotate the cylinder, but in doing so it has to lift the water which lies in the lower compartments. It is only capable of doing this through a small angle, sufficient to set the water flowing through the leak holes. As this flow continues, the preponderance against the spring decreases, and it is able to rotate the cylinder still further, until finally it completes the entire revolution. When this is done a trigger is released, the magnet makes its stroke, and the entire series of makes and breaks is effected. During the time of charging, the mechanism is at rest except for the slow movement of the cataract cylinder; when this completes its rotation, it gives the order for the change, and then there occurs a moment of activity when all the parts fulfil their functions, to be followed by another period of rest.

"We will now turn to the devices by which the cataract cylinder controls the motive-power magnet—the valve gear, as it were, of the distribution. On the spindle of the cataract is a light disc *l*, with a notch cut into its periphery at one part. On the edge of this disc there runs a roller, carried at the end of a horizontal lever, which is pivoted at its other extremity to the base-board behind. On the upper side of this lever there is a projection or catch which normally stands before the toe of the arm *k*. This arm is connected to a series of rocking switches, with only one of which we have to do at present, viz., *i*, and it has a constant tendency given it to fly outwards, towards the spectator, by a spiral spring, the end of which can be seen to the left of *g*. Now when the notch in the disc *l* comes under the roller above it, the roller and the lever drop; the catch on the latter releases the arm *k*, which flies forward at its lower end, while at the upper end the carbon switch *i* makes contact with a fixed terminal. The effect of this contact is to put the magnet into a shunt circuit from the charging main. The magnet is thus excited and makes its stroke, the speed being modified by a dashpot below, into which the core descends. The descent of the armature effects two operations; it partially rotates the shaft *t*, winding up the spring of the cataract by aid of a pair of toothed wheels, and it then restores the arm *k* and the switch *i* to their former positions as shown in the figure, cutting off the current from the magnet, and permitting the core to be raised by the spring *o*.

"The shaft *t* of the distributor carries a ratchet-wheel, which is turned by a pawl, *v*. This pawl is pivoted to an arm loosely centred on the shaft, and connected by a link, *u*, to the magnet core. There is a catch, worked by the rod *r*, which falls between the ratchet teeth and prevents the shaft being turned too far. Thus, at each stroke of the magnet the shaft is turned a certain definite amount, and it is by this rotation that the various changes of contact are made. There is a third connection, *p*, joining the armature to the spring *n*, which is coupled to a bracket fixed to the arm *k* and moving with it. When the armature descends, this spring is strained, tending to move all the switches connected with the arm *k* into the position shown in Fig. 1. These switches, however, are for the moment locked, and cannot move. But when the magnet stroke is nearly completed, a washer on the rod *p* comes in contact with a trigger arm, and, releasing the switches, allows them to be moved into their normal position, breaking the magnet circuit at *i*, and permitting the spring *o* to again raise the armature. In returning, the toe of the arm *k* raises the roller level, and sets the roller again on the edge of the disc. We have thus traced the governing and motive appliances through an entire cycle; we have seen that the cataract revolves until it releases the arm *k*, the contact *i* is then made, the magnet attracts its armature rotating the shaft and winding up the spring of the cataract, and then the contact *i* is broken and the armature is drawn up.

"We now come to the electrical connections. Each section of the battery is connected by heavily insulated wires to one of the vibrating contact makers *a*, *b*, *c* or *d* (Fig. 1). The contact maker *a* is shown moved back and out of place in order to illustrate more clearly the contact springs 1 to 8. The others are in their proper positions. Each contact maker is drawn towards the base-board by a spring, and is controlled by a cam, *q*, on the main shaft of the distributor. A certain part of the periphery of each cam is cut away, and when this part comes opposite a roller on the contact maker, the latter moves forward between the numbered springs on the board. During the time that charging is going on, the particular section of the battery which is in the charging circuit has its contact maker pressed firmly between the springs, the other three contact makers being held back by the cams. When the charging is suspended the contact maker is forced back, and the adjoining one moved forward, and so on. The successive changes in the charging circuit, which were described in Mr. Edmunds' Paper (*see* last week's *Electrician*, p. 81) are made by the switches at *f* and *g*. The switches at *f* are closed during charging, putting the battery section into the line. When the lever *k* is released the switches at *g* are closed, bringing in the resistance in parallel with that section of the battery. Then *f* is opened cutting out the battery. The magnet immediately makes its stroke, first pushing back the contact maker *a*, and then permitting *b* to go forward. The switch *f* is then closed, putting section B into the charging circuit, and the switch *g* opened cutting out the resistance. It is specially noticeable that the current is never interrupted in either circuit, and consequently there is no sparking at the contacts, and no wear. A spark occurs at *i*,

Digitized by Google

due to the self-induction of the magnet coils, but the contacts are here of carbon and always keep clean.

"So long as the cells are not fully charged the distributor continues in action, feeding the sections one at a time. But if this were to continue after the charge was complete the result would be the evolution of gas and a waste of energy. To prevent this there is provided a polarised switch, not shown in the illustration; as long as the electromotive force of the battery does not exceed a given amount this switch remains inoperative, but upon a slight surcharge it connects the two parts of the main directly together, and it maintains the connection till the cells have been sensibly drawn upon. The switch then again comes into action and restores the function of the distributor. Partly owing to this device, and still more owing to the intermittent method of charging which characterises the Edmunds' system, there is no evolution of gas from the cells. The mouths of the containing vessels are filled with a cake or cover of paraffin wax, which stands an eighth of an inch clear of the acid, and has only a small passage through it. There is no foaming or spitting of acid, and no waste to be made up. The intervals of rest which the cells enjoy between each charge seem to have a very beneficial effect upon them, allowing the chemical changes in the plates to complete themselves at leisure.

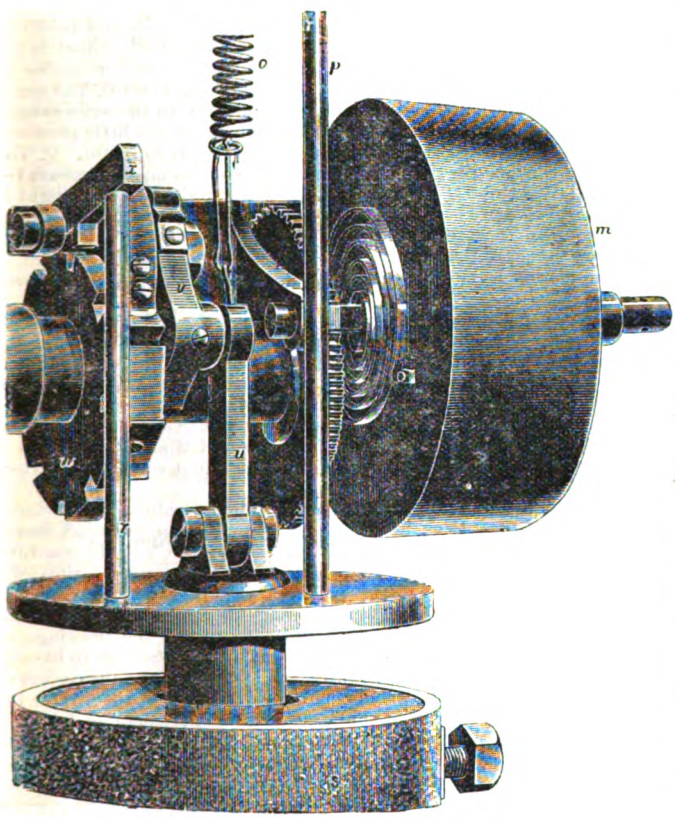

FIG. 2.

"One other mechanical feature remains to be noticed. This is the counter which registers the revolutions of the main shaft. From its indications there can be calculated the amount of electricity the consumer must pay for. The entire system is based on the assumption that the charging current is kept constant; with the usual size of cells it is 70 amperes, and by multiplying this number by the revolutions of the shaft and by the number of minutes of charging which occur during a revolution, a product is obtained expressed in ampere-minutes."

Electroliers.—In his presidential address to the Society of Architects Mr. W. Howard Seth-Smith says:—"Electric lighting has revolutionised the old gasaliers and brackets, and well illustrates the effect of science on art. Great credit is due to the leading manufacturers for the development of beaten copper in the foliated parts; copper is too soft constructionally, but harmonises beautifully with brass. One great principle in all artificial lighting is to have no naked burners, but to diffuse the light through ground glass or silk. Wrought iron, the beauty of which was suddenly appreciated seven or eight years ago, is daily improving in design, more especially under the hands of several excellent firms."

LEGAL INTELLIGENCE.

King, Brown and Co. v. The Anglo-American Brush Electric Light Corporation.

This action came before the Court of Session in Edinburgh on Tuesday. The pursuers are Messrs. King, Brown and Co., of Rosebank Electric Works, Broughton-road, Edinburgh, and the defenders are the Anglo-American Brush Electric Light Corporation (Limited), of York-place, Edinburgh. The action is brought for the reduction of letters patent obtained by the defenders in October, 1878, and other papers for "improvements in apparatus for the generation and application of electricity for lighting, plating, and other purposes," material parts of the alleged invention not being new or original. The defenders claim to be the patentees of, and the proprietors of, the alleged invention described in the letters patent referred to, and of the alleged letters patent themselves. The letters patent are dated 18th and sealed 25th October, 1878; the provisional specification was left at the Office of Patents, 18th May, 1878; the final specification was filed 18th November, 1878, the title of the alleged invention being "Improvements in apparatus for the generation and application of electricity for lighting, plating, and other purposes." On 10th January, 1882, Sir Henry James, Her Majesty's Attorney-General for England, granted his fiat giving leave to defenders to file a disclaimer and memorandum of alteration of said specification, and thereafter, on 11th January, 1882, the defenders filed the memorandum of alteration and disclaimer dated 8th December, 1881. Thereafter the defenders, on 14th February, 1885, requested leave further to amend said specification, and the Comptroller-General of Patents granted leave so to do, and Her Majesty's Attorney-General for England on appeal affirmed said decision. The pursuers state that the defenders' alleged letters patent, as amended and disclaimed, are invalid, in respect—1. The alleged invention, and, in particular, what is claimed in the 2nd, 3rd and 7th claims, was not, at the date of the alleged letters patent, the subject-matter of a grant of letters patent within the meaning of the Patent Acts. There is no ingenuity or invention displayed in the said invention, and, in particular, claims 2, 3 and 7. 2. The specification, even as amended, was disconform to the provisional specification, and claims an invention different from or not embraced in that disclosed in the provisional specification. 3. There is no sufficient distinction between what was old, or was in use and known at and prior to the date of the said letters patent, and what was new or claimed as new by the said alleged inventor. Further, there are claimed as new, inventions which were old and well known at the date of the said patent. 4. The alleged invention was not new or original. At least material parts of the said alleged invention, and in particular the inventions claimed in claims 2, 3, 4, 5, 6, and 7 of the defenders' specification, disclaimed as aforesaid, were not new or original. The said letters patent, in so far as they relate to commutators and what is now termed compound-winding, were not at the date thereof new or original. The alleged inventor was not the first and true inventor of the alleged invention, described or alleged to be described, in the said letters patent and relative specifications, and it was not first disclosed in Great Britain by him; it was disclosed and was publicly known and used in Great Britain prior to the date of the said letters patents. Inventions similar to or substantially the same with the said alleged invention were described and disclosed in letters patent granted to Alexander Melville Clark, No. 4,311, dated 11th December, 1875, and the relative specifications; in letters patent granted to Samuel Alfred Varley, No. 4,905, dated 19th December, 1876, and the relative specifications; and in a communication to the Royal Society of London on 14th February, 1867, by Charles Wheatstone, F.R.S., "On the Augmentation of the Power of a Magnet by the Reaction thereon of Currents Induced by the Magnet itself," published in the *Proceedings* of the said Society for 1866 and 1867, Vol. XV., page 369; and the same was well known to electricians in Great Britain and used by them. The said alleged invention was also publicly made and used by Siebe and Gorman at their works, 187, Westminster Bridge-road, London, in 1876-77; and by the Electric Engineering Company at their works, Mill-street, Ancoats, Manchester, during the last twenty years. 5. The said alleged invention was not, at the date of said alleged letters patent, of any practical utility. 6. The said specification does not so describe the alleged invention as that a workman of ordinary skill could understand the same, or make or use the alleged invention without further invention. It does not sufficiently disclose the nature of the alleged invention, or how it is to be perfected; in particular, no means of carrying out claim 7, so as to be useful, is shown. 7. By the disclaimers the invention originally claimed is enlarged and extended beyond, and is different from what was described in the provisional specification, or in the original final specification. 8. The specification as amended is not in conformity with the title. The defenders have threatened the pursuers with legal proceedings and liability in respect of the manufacture, use, or sale of the alleged invention said to be covered by the letters patent, and in particular of compound-wound dynamo machines. This, the pursuers state, has very seriously affected their business. The defenders admit having threatened the pursuers with legal proceedings, and that the proceedings threatened were carried out against the Orient Steam Navigation Company, who were using machines made by the pursuers. An action against the Orient Company is pending in the High Court of Justice, England, and, it is stated, the same questions are raised there as in the present action. The pleas in law for the defenders are:—1. The averments of the pursuers are not revelant or sufficient to support the conclusions of the summons; and 2, the averments of the pursuers being unfounded in fact, and their pleas untenable in law, the defenders are entitled to be assoilzied from the conclusions of the summons, with expenses.

Proof in the action was begun on Tuesday. The pursuers were represented by Mr. Graham Murray, Mr. C. S. Dickson, and Mr. Daniel; and

Digitized by Google

the defenders by the Dean of Faculty (Mr. William Mackintosh, Q.C.), and Mr. Jameson.

JOHN IMRAY, manufacturing and consulting engineer, was the first witness called for the pursuers. Examined by Mr. Graham Murray, he explained the principles upon which a dynamo electric machine is constructed and the method of its working, with special reference to the methods of winding the field-magnets. In connection with this case he had examined the Hadden and Varley specifications. The former was divided into four divisions. The original patent, in which the provisional specification was stated, gave three divisions—on the construction and use of the armature, the construction of the commutators, and the arrangement of the wires. There was also a fourth division, which was afterwards cut out.

Q. Looking at the provisional specification, how many inventions do you see foreshadowed?—*A.* I can only see one—particulars as to the construction of the commutators with wearing segments attached in a particular way. At the date of the patent in question commutators were old; the construction of the cylindrical form of commutator was also old. The segments shown in the model might have been produced in the old commutators. Turning to the patent as amended, the first claim was for armatures; the second was for a commutator cylinder, the description of which was almost word for word the same as in the provisional specification; the third claim was appropriated to a particular arrangement shown in the drawing; the fourth claim was also for a particular instrument shown in the drawing; the fifth claim was for a commutator having a metallic insular segment attached. Shown a commutator with an insular segment marked "T," witness said he found no hint of that in the provisional specification. It was a perfectly different and distinct apparatus, having different and distinct objects from the object served by making the sub-segments of a commutator detachable. Claim 5 was for a particular commutator, which, instead of making those insular segments entirely insulated, joined them on to the segments of the next brush. There was no hint of that in the provisional specification. In claim 6 there was again the introduction of the insular "T" into the commutator, of which there was no hint in the provisional specification. *Q.* Was there any invention in separating the commutator into two bits and then putting them together with screw nails?—*A.* No. Practically, in the commutator described in the specification there was nothing else whatever but the dividing of it into two bits and then putting it together again with screws.

Witness was shown and described a commutator made in Manchester, and used before the date of the patent. It consisted of two cylindrical segments insulated from each other, and on each there was a semi-cylindrical bit of brass on which the brushes ran. That could be properly described as a commutator in which sub-segments are in proper electrical connection; while there was another exterior segment attached to the sub-segment by a screw or other mechanical device, making a wearing surface. It was, in fact, a combination of sub-segments, wearing segments, and screws. *Q.* Had the incandescent light proved a success at the time of the original specification in 1878?—*A.* No; practically it had not come into use. *Q.* Was the question of the division of the current completely understood, so as to set up lamps in parallel?—*A.* No, because there being no lamps to set up there were no experiments made (laughter). The arc lamps were almost the only ones used at that time. *Q.* Were the arc lights at that time used in series, or just one light to each circuit?—*A.* Almost in every case each lamp had its own dynamo machine to work it. *Q.* Do you find any indication in the Brush specification of the application of this machine for the purposes of electric lighting at all?—*A.* No. In the specification the object stated was to maintain a permanent field for the purpose of electro-plating. The seventh claim was not for a machine so constructed; it was for a combination of helices. At that time two helices upon a magnet were old. *Q.* To a certain extent does self-regulation follow from a permanent field?—*A.* They are not at all identical; but the one follows as a natural consequence of the other. *Q.* Do you find here that Mr. Brush claims a proper shunt as well as a series shunt.?—*A.* Yes.

Q. Supposing a machine to be shunt-wound or series shunt-wound, and to attain thereby a certain power of self-induction, does it necessarily follow that you have got a machine of constant potential?—*A.* No. That would depend upon how the wires were proportioned to the work. In a pure shunt you would never have a constant potential. *Q.* For electro-plating, about which Mr. Brush is talking, was there then any particular necessity for having a constant potential?—*A.* No. *Q.* On the other hand, for electric lighting, as now carried on, there was a great need of constant potential?—*A.* Yes. *Q.* Do you find in Brush's specification the slightest indication, first, of any desire for constant potential and second, of giving the means by which it is secured?—*A.* No, I find no hint of it. From the condition of electric lighting at that period I do not think it is possible that it could have suggested itself, because there was no call for it.

Q. If a machine was made in accordance with the terms of Brush's specification, would it be quite possible to make it and arrange it according to the series-shunt plan of winding and yet make it non-regulating?—*A.* There might be a condition in which it was self-regulated, and there might not. In Mr. Varley's specification for producing electric light, two years before Mr. Brush's, there was described a dynamo machine and an arc lamp. In the final specification it was stated, "Part of the electricity developed by the machine is devoted to maintain the magnetism of soft-iron magnets, and the remaining portion is used to produce the electric light. The method I prefer is to wrap the soft-iron magnets with two insulated iron wires, the one having a larger resistance than the other." That described the series-shunt in every detail. At the time this specification was written it was quite common to use the word electricity as equivalent either to electric current, which was one thing, or electric energy, which was another.

Q. If you read the word "electricity" as "electric energy" is it quite true that part of the electricity developed by the machine is diverted to maintain the magnetism of soft-iron magnets and the remaining portion used to produce the electric light?—*A.* Yes. In maintaining the magnetism of the magnets there is a definite consumption of the electric energy. *Q.* It has been suggested that what Varley described here was not a series-shunt arrangement, but what is called a double shunt?—*A.* I do not agree with that. It would not be consistent with this description in the specification. I cannot conceive any use for a double-shunt arrangement, and if there was a double shunt there would have to be three currents. Varley, he continued, did not give any drawings with his specifications at the time the series-winding and the shunt-winding methods were known. It was quite a simple thing to put the two together. He supposed Varley thought there was no invention in it. He had no doubt that had been done by Varley; it was clearly described at all events. Varley also gave no indication of the different resistances that were to be proportioned to each other; but he stated that the shunt coils would be of greater resistance. *Q.* Do you find anything in Brush's that is not disclosed in Varley's?—*A.* No; the very same words are applied to the description. *Q.* How do you read Brush's claim standing alone?—*A.* I think it is a combination of shunt-helix and of series-helix of electric magnets. *Q.* Do you find any hint of that in the original specification?—*A.* Not of that combination.

Cross-examined by the DEAN OF FACULTY: Mr. Varley made a new invention. *Q.* Was compound-winding not a fresh improvement upon series-winding and shunt-winding?—*A.* At that period there was not much call for it. *Q.* In 1878, whether there was much call for it or not, was it not a distinct improvement?—*A.* Yes, in 1876 and 1878.

Q. So that compound winding was disclosed in Varley?—*A.* Yes. *Q.* And you do not dispute that compound winding was also disclosed and described in Haddan?—*A.* No. *Q.* The question raised was, who invented it?—*A.* There is no question about that (laughter). *Q.* There were series or shunt machines previous to Varley and Haddan?—*A.* Yes. *Q.* The series machine had serious faults.—*A.* It had some faults. *Q.* In the series system when the resistance was increased the machine yielded too little pressure, and, therefore, too little magnetism was produced?—*A.* No doubt. *Q.* The shunt machine, when the resistance was great, gave too much pressure?—*A.* Yes. *Q.* While, on the other hand, when the resistance was slight it gave too little pressure?—*A.* Yes. *Q.* So that both of these machines were unsatisfactory in their resistance?—*A.* Not at that period. The only unsatisfactory part was this, that if you had a series machine and applied it for electro-plating, as soon as your outer circuit was broken you lost your field-circuit.

Q. Is it the case that the compound machine tended to compensate these defects by producing constant potential?—*A.* Yes. *Q.* A shunt series machine tends to reduce constant potential more or less according to the excellence of its proportions?—*A.* No doubt. *Q.* And that was a distinct improvement?—*A.* It has come to be of great importance. *Q.* Do you dispute that Haddan's specification describes a system of compound winding?—*A.* It described a system of compound winding, and also a system of shunt winding. *Q.* And the claim for shunt winding was afterwards disclaimed?—*A.* Yes.

Q. I suppose it described it so that a workman of ordinary skill would, if he followed the directions in R. Haddan's specification, construct necessarily a compound wound machine?—*A.* He could do so, and the machine so constructed would tend to constant potential more or less approximately, according to the proportions used. In Varley's specification there were no drawings, but in Haddan's there were drawings showing the different forms of his compound winding. Witness declined to regard the drawings as throwing any light upon the proportions which the wires were to have to one another. Assuming all to be wire, the wire which was the circuit of high resistance would in breadth be about a third or fourth of the wire in the circuit of low resistance; and in volume, which was the square of breadth, it would be about a ninth. He presumed that the thin wire was longer than the thick one, and no doubt would affect the resistance.

Q. So that, taking the degree of resistance in the one coil and in the other, as indicated by the drawings, would the resistance of the large or series coil be very small in proportion to the resistance of the shunt coil?—*A.* Yes; but as the coil is in connection with the outer circuit, that gave no indication. *Q.* Suppose a workman were to follow the drawing, he would make the shunt coil of very high resistance in proportion to the series coil?—*A.* Yes. *Q.* If a workman not only took the letterpress, but the drawings, and were to construct a machine with the coils having this proportioned resistance would not his machine not only tend to constant potential, but would it not produce a pretty close approximation of constant potential?—*A.* In some particular cases, when you had certain particular circuits, lamps and leads. Continuing, he said that his view was that Varley's specification sufficiently described compound winding, and while there was no claim in his specification applicable to compound winding as so described, his directions of the mode of connecting up his machine produced compound winding. The main object of the specification in certain lines indicated was exactly the same as Haddan's—to keep up a permanent magnetic field. *Q.* "Part of the electricity developed by the machine is diverted to maintain the magnetism of the soft-iron magnets, and the remaining portion is used to produce the electric light." Is that a quite correct description of an ordinary shunt machine?—*A.* It does describe a shunt machine. *Q.* Anybody reading that passage by itself would understand that a shunt machine was meant?—*A.* If he did not know anything else.

Re-examined by Mr. DICKSON: In Haddan's specification there was no suggestion from beginning to end of constant potential, nor was there any definite proportion between the lesser resistance and the greater. In the various figures attached to the specification the proportions were not given. In the letterpress there was no indication of the special circumstances in which constant potential could be obtained, nor was there anything to suggest that that was the end desired. In Varley's specification the simple shunt was clearly not contemplated.

This concluded the evidence of the witness, and the Court rose.

WEDNESDAY.

The case for the Pursuers was resumed to day before Lord Trayner.

RICHARD MARRIOTT, manager to Millwright and Co., electro-platers and gilders, Birmingham, deposed that in June, 1870, his firm purchased from Henry Wild and Co., Manchester, the commutator produced, and it had been in use ever since. They also purchased commutator rings from Wild and Co. of the pattern produced. There were wearing segments applied to the outside of the commutator, and they had been in use by his firm since 1870.

In cross-examination witness stated that his commutator was identical with the one marked No. 27.

HENRY BOURNE, electro-plater and jeweller, Birmingham, deposed that in 1869 he purchased an electrical machine from Wild, of Manchester. He produced the commutator belonging to that machine. The outside rings were in all cases fastened with screws. He produced another commutator, supplied by the same firm in 1874. The two commutators, Nos. 27 and 28, were identically the same as his, except that thoy had copper rings, or detached segments, while his were of gunmetal. The attachable segments were renewed from time to time.

Cross-examined: The screws in his commutator were fastened from the inside, but that made no difference in the work.

JOSEPH SHILVOCK, pattern-maker and metal worker, in the employment of last witness, said the Wild electrical machine had been in the works as long as he had been there, for seventeen years at least. He identified the commutator produced by his employer as part of the machine.

WM. FREDK. HOBDAY, managing clerk to the Electric Engineering Company, Manchester, produced the journal of Henry Wild and Co. from 1863, showing that they had supplied commutator rings to Mr. Bourne and many others.

ROBERT MARSH, employed in the fitting department of the Electric Engineering Company, Manchester, being shown Nos. 27 and 28 commutators, along with that produced by Mr. Bourne, said they were all in the same form as made by his firm since 1872. The attachable segments were fitted on with screws from the inside, which he considered much better than if fitted from the outside, because, if fitted from the outside, the head would get worn away, and in supplying new rings the screws would have to be drilled out.

Cross-examined.—The one half of the commutator was insulated from the shaft by a vulcanite collar, and the other part was in connection with the shaft.

Dr. JOHN HOPKINSON, F.R.S., examined by Mr. GRAHAM MURRAY, deposed that he had written several Papers in the *Transactions* of the Royal Society on electrical machines. He had directed his attention to Haddan's specification of Brush's patent. *Q.* What is the invention adumbrated in the original provisional specification?—*A.* Simply attaching to the sections of the commutator wearing pieces which can be removed as they wear away. *Q.* Does claim 2 in the complete specification, as explained and amended, correspond with the claim adumbrated in the provisional specification?—*A.* Yes. Claim 3 is a claim for the addition of certain screws for the purpose of attaching the removable segments. The fourth claim is for certain insulated segments "T." The fifth claim is for a particular way of attaching segments "T" to the neighbouring segment. The sixth claim is for the omission of one or two segments "T" from the commutator. *Q.* Do you find anything in the provisional specification that at all indicates the invention which is claimed in claims 4, 5 and 6?—*A.* Nothing whatever. The object of the insulated segment "T" is to ensure equal wear. So far as they are insulated, they are for disconnecting a section of the armature from the commutator. There is no disclosure of that in the provisional specification. Claim 2 is for a commutator cylinder with a hub. At the date of Haddan's patent, in 1878, commutators were old, and in most cases the insulation was a cylindrical hub, to which the segments of the commutator were attached. *Q.* So far as Claim 2 is for a commutator cylinder, in cylindrical form and containing a hub, do you think it possible to read that claim as an invention of a commutator cylinder?—*A.* No. *Q.* In what way do you read claim 2?—*A.* As a claim for attaching wearing segments to sub-segments connected with the wires of the armature.

The DEAN OF FACULTY objected to the two last questions; but the objections were repelled by the Court.

Q. Coming to the portion of Brush's specification which deals with the seventh claim, what was the condition of electrical knowledge and practice in 1878 as regards incandescent lighting.—*A.* The incandescent light was first disclosed as of any practical value at the end of 1879 or early in 1880. *Q.* Until the discovery of the incandescent lamp was there any particular reason or object in having dynamo machines which would maintain a constant potential?—*A.* No, there was no use for such a machine. In Brush's patent there is no indication of a desire to have a machine of constant potential. *Q.* Assume a machine made according to Brush's patent; is it possible that that machine would not have a constant potential?—*A.* It is exceedingly probable. *Q.* What else would you require to have, beyond what is in the specification, in order to have a constant potential?—*A.* You would require to know how large the machine is to be and what speed it is to run, and also the difference in the diameter of the wire. It depends on the proportion of the windings being accurately determined, and that would depend on the speed the machine is to run.

Q. After the discovery of the incandescent lamp, who first began to make constant-potential machines?—*A.* I really do not know, but it must have been about 1881 or 1882. *Q.* What do you find is desired in Brush's specification?—*A.* To maintain the magnetism of the magnets even when the machine was doing little or no external work. He speaks of applying his machine more particularly to electro-plating. Turning to Varley's specification, I find there a disclosure of a certain manner of winding. It discloses a winding of the magnet with two coils, one at the higher and one at the lower distance. The one at the higher distance is constantly in circuit, so that whether external work is being done by the machine or not, electricity would constantly flow through it. The coil at the lower distance shows a series coil for the electric light. *Q.* Does he, according to your view, disclose it in such a way that an ordinary workman could have made a machine?—*A.* Yes; there is no ambiguity about it. *Q.* Does he, any more than Brush, disclose a method of making a machine with a constant potential?—*A.* I do not think either of them had in view at all the desirableness of a constant potential. The light spoken of in the specification is an arc or semi-arc light. *Q.* What part of the specification shows that, when the remaining portion is used to produce the electric light, you are led to believe that that portion also magnetises the magnet?—*A.* He says, "when the electric light has been produced, the greater portion of electricity passes through a circuit of less resistance," which I term the electric-light circuit. It is evident that it is to be a circuit formed of coils upon the machine for the purpose of magnetising the magnets, and that the current produced should afterwards pass through the carbons of the lamp.

Q. It has been suggested that the method which he describes was really a method for separate excitation. Do you take that view?—*A.* No, certainly not. In the specification he has described a particular machine, and he does not tell you how he can wind the magnets of this machine. The method which he has described must, therefore, be applicable to the machine described in the body of the specification. Referring to that machine, I find that he there describes perfectly clearly the way in which the sections of the armature are to be arranged, how they are to be connected together, how connected with the commutator, and how the several segments of the commutator are to be connected with each other. These preclude completely the use of a special portion of that machine for the purpose of exciting the magnetism. The words in the specification also entirely preclude the idea of excitation by a separate machine. So far as series shunt-winding is concerned I find everything disclosed in Varley that is disclosed in Brush. I find in Varley's dynamo machine, No. 29 of productions, that the wires are wound with magnets of different resistance. *Q.* Is that machine one that would be fairly made in accordance with Varley's specification?—*A.* Yes, although there is a little difference in the commutator. [Shown Nos. 37 and 38 of productions.] These are models of a series-shunt or compound-wound machine.

Mr. GRAHAM MURRAY: I shall prove afterwards that the machines of which these are models were made by inexperienced persons, who simply followed Varley's specification.

Cross-examined by the DEAN of FACULTY: *Q.* Your evidence is to the effect that the machine which Haddan describes is substantially the same as that described by Varley?—*A.* In respect of the winding it is. *Q.* I suppose you do not dispute that the series-shunt arrangement was a marked improvement on any previous arrangement?—*A.* It only became a marked improvement by the subsequent discovery of the incandescent lamp. The advantage of it was really this: When the incandescent lamps were introduced it became essential that they should be worked at a definite pressure. By using the series as well as the shunt-winding you were enabled to keep up the pressure. He demurred to the suggestion that it gave the means of accomplishing an important result which did not exist before, as part of Varley's machine did exist before. Haddan described a series-shunt machine sufficiently to enable a workman to construct a series-shunt machine, but he gave no information as to how to make that machine give a constant pressure; and there was a want of scale of the proportions in the diameter and length of the coil, and of definite speed. *Q.* Will any proportion of the winding give substantial constant potential at some particular speed?—*A.* I can hardly say offhand. In many machines, no doubt, any proportion would give you that; but there were no instructions here to meet the case. A workman would reach constant potential by finding it out for himself by experiment. He would not find it out by Brush's patent.

Q. Could you give general directions which would secure constant potential?—*A.* No doubt you could give general directions, but you have to include speed and dimensions. *Q.* Did not Brush actually supply dynamo machines of substantially constant potential as early as 1879?—*A.* I never heard that. *Q.* Do you not know it for a fact?—*A.* Certainly not. Proceeding, he said he was engaged as a witness for Messrs. Crompton in their recent suit with the Brush Company. In his affidavit in the case he did not give all the points of objections to the Brush machine, but he gave sufficient to make out a *primâ facie* case. In 1876 Wheatstone communicated a Paper to the Royal Society "On Shunt Machines." Witness could not say that before that they were known in the market. The knowledge in Wheatstone's communication would reach skilled workmen in time. When Varley spoke in his specification of there being several well-known ways of doing this, he pointed to all classes of dynamo machines known at that time. Any one skilled in this industry would infer from his specification a shunt machine. Compound winding was then unknown as such, and when Varley spoke of preferring another, he meant compound winding. The first three lines of the specification describe shunt, but they did not preclude compound winding. Varley's machine was not a bad machine in its day; but it would be useless in comparison with the machines of to-day. Prior to Brush's patent he had never seen or heard of any compound-wound machines.

Re-examined: A photograph of a rough sketch in a book belonging to Varley would indicate a compound winding.

Mr. SAMUEL VARLEY, the next witness, said that for many years he had devoted attention to electrical machines. In 1852 he joined the Electric International Telegraph Company. From 1861 to 1866 he tried to make a self-exciting dynamo machine, and in the latter year, in conjunction with his father, Cornelius Varley, he managed to make a self-exciting machine, for which he took out a provisional specification. That machine was in the South Kensington Museum and in the Inventions Exhibition. In 1885 he got a gold medal for it as being the first

Digitized by Google

self-exciting dynamo. 1876 was the date of his patent in connection with this case. At that time there was no incandescent light. The only light really known was the arc lamp. The specification described among other things a certain method of winding the magnets of a machine. *Q.* According to your view what method of winding is there described?—*A.* What is known as series shunt. He had a machine constructed in accordance with his specification in the works of Siebe and Gorman, of Westminster. It was commenced in 1876 and was finished in the early summer of 1877, and it was used for producing electric light. He had in his possession a private note-book in which he wrote, before the specification was lodged, a description of a series-shunt machine; and a diagram in that book described such a machine. In his specification he said "part of the electricity developed in the machine is devoted to maintain the magnetism of the soft-iron magnets, and the remaining portion is used to produce the electric light. There are several well known ways of doing this, but the method I prefer is," &c. The first of these was Wheatstone's plan, and it was known as the shunt machine. There was also Wylde's plan of two commutators, and a certain number of bobbins were used only for exciting the field. In his specification he proceeds to describe the method which he preferred. *Q.* You say you do not claim that in the patent?—*A.* When he was drawing up the complete specification he thought it advisable to consult the *Philosophical Magazine*, in which there were published Papers read by Sir Charles Wheatstone and Dr. Siemens, describing their independent discoveries of the dynamo principle. These Papers were read in February, and there was a Paper read in March by his late brother, C. F. Varley, in which he suggested that the shunt which tended to assist the permanent field-magnets should be wrapped around the field—that was to say, that the electric current should be utilised. It seemed to witness at that time that that left him very little to claim, and he wished to avoid legal differences with his brother. In other words, he came to the conclusion, after consultation with his patent agent, that the description in his brother's patent was of the principle of the series-shunt, with the result that witness did not claim that in his patent. At that time he understood the significance of shunt winding. *Q.* Your specification goes on to describe a certain form of lamp for the maintenance of an arc; was the series-shunt winding necessary or useful for that lamp?—*A.* It was absolutely necessary. It would not have worked with either plain series or plain shunt.

Cross-examined by the DEAN OF FACULTY: Was the machine in Court made by Siebe and Gorman in accordance with his patent?—*A.* The machine in Court was worked at Siebe and Gorman's both experimentally and for a practical purpose. It was worked in order to take a photograph of an ice machine constructed at the works. On that occasion Mr. Siebe, the foreman, and the photographer were present. Witness was not present. Mr. Siebe was now dead, but the foreman and Mr. Gorman were alive, and they were both here. The machine was kept in the works. He was a partner of the firm only as regarded this patent. His connection ended about 1880. He had seen the machine work often. It lay in the works till it was produced in connection with the Crompton case. He never sold a machine made in the terms of his patent; and he never made any machines like it. *Q.* Part of the electricity developed in the machine is diverted to maintain the magnetism of the soft-iron magnets, and the remaining portion is used for the electric light. This is in your specification. Does it apply to a series machine?—*A.* Certainly. *Q.* Then your reading of the word "electricity" in this patent is that it means "electric energy?"—*A.* Certainly; and that is the meaning I apply thoughout, and I did not know any difference between electric energy and electric current. At that time Wheatstone's machines were known, and Gramme's and Wylde's were known in the market, and were sold and worked.

Q. In 1876 was a shunt machine known in the market and worked, or had it merely been described in a Paper before the Royal Society?—*A.* It was commonly known in practice in the British Telegraph Company. I constructed a Gramme machine on the shunt principle. *Q.* Was there any dynamo machine constructed and used on the shunt principle prior to 1876?—*A.* Yes. *Q.* Where?—*A.* In the British Telegraph Company. *Q.* For the purposes of telegraphy?—*A.* For the purpose of separating magnetic iron ore from unmagnetic iron ore. I constructed myself in 1874 a magnetic separator, and I used a Gramme machine as a shunt machine. *Q.* Were there any other machines on the shunt principle which were so used?—*A.* I am inclined to think that the shunt at that time was common knowledge, but of any other shunt machine I am not aware. These machines being well known, he thought he had invented a new machine which was not well known. He regarded compound winding as an important matter; but he did not know the full importance of it at the time. His lamp would not work without it. He did not claim the patent, for the reason he had explained, that his brother had read a Paper describing a mode of working which, witness feared, might be an anticipation. His brother's communication, which was sent to Prof. Stokes and read to the Royal Society in March, 1867, contained the following passage:—"The force expended in the shunt is wasted in heat; but a secondary wire on an electro-magnet or a copper cylinder would very greatly add to the power of maintaining the magnetism and not consume the useless force now wasted on the shunt." [Shown a diagram connected with the Paper.] There was in that a secondary wire in addition to the shunt.

Q. Is there anything in the passage to suggest that the secondary wire was to be excited by a current of electricity passing through it?—*A.* My brother's description gives two alternative suggestions, one a simple copper cylinder, and the other a wire on which the work was performed. The wire drawn on the diagram was the same as a copper tube. He did not claim the patent because he was afraid of being involved in litigation with his brother. He did not abstain from claiming the invention because Gramme or Wylde had anticipated what he described. *Q.* In your specification you describe a machine which was constructed for the purpose of separating the development of magnetic and electric forces. Do you now think it is possible to separate the development of magnetic forces?—*A.* Yes, I do. *Q.* Do you still consider that you thereby greatly increase the magnetic potential in the bobbins?—*A.* Yes. *Q.* Does that greatly increased magnetic potential in the bobbins become at a later stage converted into electricity?—*A.* That becomes converted into electricity. *Q.* Of corresponding high potential?—*A.* I should be doubtful whether I was strictly correct about the energy. *Q.* Was not the whole object of your machine to get an increased amount of energy?—*A.* That was not the sole object. My main object was to get a more perfect machine and get a greater amount of energy, but my theory of reaching that was a mistake. *Q.* Do you still think it possible to use three groups of bobbins, as you propose?—*A.* Yes. *Q.* Did you ever see or hear of a dynamo where there was an odd number of groups of bobbins?—*A.* No, I think not. You took great interest in the recent litigation of the Messrs. Crompton?—*A.* Yes. *Q.* You were very much disappointed when the case came to an end?—*A.* I was. *Q.* I believe you wrote to the solicitors of the company expressing your surprise that they should not have had faith enough to fight the case?—*A.* Yes. *Q.* Upon the Messrs. Crompton declining to fight the case did you ask an interview with Mr. Sellon, vice-chairman of the Brush Company?—*A.* I asked for an interview without prejudice.

Q. In that interview did you propose that if the Brush Company gave you a certain salary you would make it impossible for anyone to challenge your patent?—*A.* No, I did not. *Q.* Did you propose that the Brush Company should take you into their services and give you a salary?—*A.* I stated to Mr. Sellon that my friends had advised me to say that as I had considerable sympathy with the shareholders of the Brush Company, and held a sort of good-will—although I had lost my patent rights—if they offered me an appointment which my friends considered I might honourably accept, I should accept it, and publish an account of what I had done. He received a letter from Mr. Sellon, dated 31st Nov., 1887, stating, "I told you we are unable to recognise in your specification any point which bears upon our right in this matter; but whether this were so or not our acceptance of your candid suggestion that the Brush Company should purchase your silence, and thus, in your opinion, safely secure our royalty by giving you a salaried appointment, is such as could not for a moment be entertained." *Q.* Do you repudiate the construction Mr. Sellon put upon your proposal?—*A.* I do; and in my reply of 15th December I said: "On the advice of some of my friends I sought an interview, and had you seen your way to make any offer, which you did not, and which my friends considered I might honourably entertain, I should have recognised I was selling my birthright for a mess of pottage" (laughter).

Re-examined by Mr. MURRAY.—Mr. Sellon called and wanted to buy witness's machine; but he would not sell it. Mr. MURRAY.—The Brush Company would, no doubt, have kept it in a glass case (laughter). *Q.* Had you known the possibilities of compound winding in electric lighting, would you have run the risk of encountering your brother by taking out a patent? *A.* I am sorry I ever read those Papers.

This concluded the evidence for the day, and the Court rose.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *November 17th*, 1888.

A decision has just been rendered against the American Bell Telephone Company by the United States Supreme Court, on the question of the right of the Government to institute a suit for the cancellation of patents. This decision is quite unexpected, and as it is the first time that the Courts have gone against the company in a long while, it may not be amiss to rehearse the facts briefly. Some time ago Solicitor-General Jenks, acting as attorney for the Government, brought a suit in equity in the United States Circuit Court of Massachusetts to have the Bell patents cancelled, on the ground that they were obtained by fraud, and that Bell was not the first inventor of the telephone. Against this the American Bell Telephone Company filed a demurrer, in which they asserted broadly, without paying much attention to any other issues, that the United States, in the absence of a specific statute to that effect, had no right to bring a suit to cancel a patent for an invention. Judge Colt, of the Circuit Court, sustained this demurrer, and the matter was brought up on appeal before the United States Supreme Court at Washington, where the decision referred to has now been rendered by Judge Miller. With regard to the contention that the United States cannot bring suit to void the patent, the Court says that such a doctrine is not sound. The United States, in issuing these patents, had bestowed on the patentee rights of immense value, and if the Government, believing fraud to have been exercised to obtain this property, should find it its duty to correct this evil, and to recall these patents, the proper remedy was the one adopted by the Government in this case. As to the contention that it was possible for any individual affected by the monopoly of the patent to set up the defence that the patent was obtained by fraud, and

Digitized by Google

that, therefore, the United States should not bring suit, the Court remarked that it was impossible to suppose that the Constitution, in granting the right named to individual litigants, intended to supersede or take away the more enlarged remedy of the Government. The Court decided that the objection of multifariousness of attacking more than one patent at the same time did not have any bearing, as the two patents were issued to the same person, and related to exactly the same subject, while at the present time the Bell Company and Mr. Bell were the only parties to the defence, and their interest in sustaining the patents was the same. On the important ground of objection raised that the Bill of Complaint did not set forth any specific fraud in the securing of the patent, the Court held that the Bill was sufficiently full and explicit on this point. Of course, the Court does not say anything as to the truth of the allegations, but of those allegations themselves it says that they are mentioned with sufficient precision, and that there can be no question that if the Bill be taken as true, there is enough in it to establish the fraud in the procurement of the patents and to justify their cancellation if the Court has the necessary jurisdiction. As I have said, the decision came rather in the nature of a surprise, and telephone stock in Boston fell several points. Yet the question which arises is, what will the Government do with its decision now that it has won it? The litigation is peculiarly the property of the present Democratic Administration, which goes out of office and out of power next March. Even if all the machinery were set briskly in motion now there could be no very great headway made, and it is not to be expected that the incoming Republican Cabinet will care to have anything to do with the scandal other than to let it drop. As the Court said, the charges made against Prof. Bell were sufficient to upset the patent, and, it might be added, were sufficient also to dismiss him for ever from the society of honest men; but then there is nothing new in these charges, and Prof. Bell has already had, at the hands of the Supreme Court, a notable vindication of his character and a striking eulogium on his genius as an inventor. The Court may go back on its own record, but I hardly think it will.

You will remember that in my letter recently I referred to the purchase of the Sawyer-Man property and rights by the Westinghouse Company, and said that this step would involve new relations between the Westinghouse and Thomson-Houston Companies, the latter in its incandescent business having operated largely under the Sawyer-Man patents. It was evident that this change would bring about either a closer affiliation between the two great companies mentioned, or would throw them wider apart. When I inform you that the Westinghouse Company has now purchased the Waterhouse arc system, and that the contract between the Westinghouse and the Thomson-Houston Companies is reported to terminate on the 30th of this month, you will see at once that the two companies have agreed to differ, and that each will stand on its own bottom for electric light business in both departments. In a great many quarters the alliance now terminated was looked upon as the first step towards a wider and stronger combination, and it is evident in that the points at issue were too numerous and important to be reconciled, even in the case of two companies, that the rupture rendered altogether improbable the formation of an union of thirty or forty other conflicting interests. If competition be the life of trade we are likely to see great activity in the electric lighting fields, and in this way no great harm will come from the new conditions. It is understood that the control obtained of the Waterhouse Electric and Manufacturing Company by Mr George Westinghouse, jun., is absolute, the entire capital stock having been bought up. The Waterhouse Company now has about 5,000 lights in operation all over the country. The manufacture will hereafter be carried on at Pittsburg. The reason why the Westinghouse Company has taken up the Waterhouse system is, that the Waterhouse method of regulation, with its third brush, is regarded as the only desirable system of regulating arc lighting apparatus which escapes the patents held by the Thomson-Houston Company and supported by the Courts, with regard to the regulation of the machine by the automatic shifting of the brushes. Mr. Westinghouse seems as thorough in this matter as in others, and having made up his mind to acquire systems which shall cover the whole range of electric light and power, he will doubtless achieve his purpose as quickly as possible. It might appear that the market for electric light apparatus had been pretty well filled up in this country, so that the new business was not worth scrambling for, but we are very far from the point at which our manufacturers must look abroad for new consumers. Even our large cities, which were supposed to have all they wanted a year or two ago, keep ordering new circuits and new lights, and not a few of them are going into the business of running plants for themselves, while this wholesale class of business is supplemented by a mass of small orders which, in the aggregate, yield totals quite as large.

The time is approaching when the authorities will have to do something with regard to the law which requires the execution of capital sentences by electricity after the 1st of January. No action has yet been taken by the State, so far as I am informed, and in the meantime the Medico-Legal Society, of which Mr. Gerry, a member of the Capital Punishment Commission, is also a member, has had a committee at work investigating the subject, and that committee has now made its report. Three methods of application of electricity were proposed. One was the passing of the current from wrist to wrist through the body; another was the passage of the current from a metallic band fastened to the forehead through the body to one of the wrists, and the third method proposed placing the criminal between a metallic cap at his head and a metal plate at his feet. The committee has rejected all these methods. It has made experiments with dogs, and reports in favour of passing the current from the top of the head to a point on the spine between the shoulders. The current will cut every point of vital energy in the brain and the great nerve passages leading downward through the neck, and death will be instantaneous. It is recommended that the electrodes shall be of metal, not over 1in. in diameter, and covered with a thick layer of sponge or chamois skin. The poles and the skin and hair at the point of contact should be thoroughly wet with warm water, and the hair should be cut short. It is recommended that a dynamo generating 3,000 volts E.M.F. should be used, either direct or alternating, the preference being given to the latter. The time of passing the current should not exceed 30 seconds. The Society has not adopted the report, but will take it up at its December meeting.

Patents have just been granted to Mr. Edward Weston on a series of electrical measuring apparatus, upon which he has been at work for some time, and which it is thought by all who have seen the instruments will do great credit to this country, not only for the inventive genius shown in them, but for the fine workmanship brought to bear upon their production. One of the pieces of apparatus is a voltmeter. It embodies the idea that the current to be measured, in circulating over a coil in the circuit, which is supported freely in a uniform magnetic field, shall cause a movement of the coil due to the resultant effect of the current upon the magnetic pole. To the motion of the coil is opposed a uniform resilient resistance, so that the extent of the movement shall be directly proportional to the strength actuating the current, or when the current passes through a high resistance to the E.M.F. of the current. I have no doubt that some of these instruments will soon be seen in England, where I feel confident they will excite admiration.

New York City is about to lose two of its features, which might fairly be spoken of as landmarks. I refer to the two great masts which have stood in Union and Madison-squares for the last six or seven years. These masts reached a height of over 150ft., and carried at the top a crown of six Brush lights. These lights could be seen over the housetops for miles round. Both in winter and summer their rays converted the squares that they illuminated into dainty little fairy lands. In summer time, one of the prettiest sights in the city has been these squares, filled with playing children and well-dressed people lounging on the benches under the leafy trees, through whose waving branches shot insistant gleams of light, brightening the lawns and flowers, and turning the broad walks into pathways of silver. I have never heard anybody speak of the spectacle except with pleasure, and yet it has to be admitted that

Digitized by Google

a great many people living or doing business in the neighbourhood complained of the glare of the lights as a nuisance. Anyway, it has been decided that these lofty towers are a failure, and their place has been taken by pole-lights distributed about the square and among the trees, where, to my way of thinking, their effect is greatly diminished by their being shut in by the foliage. Before this the effect of the tower lamps on the square had been that of a soft, subdued moonlight, whereas now all that one gets is a sharp alternation of glare and gloom, so that one is apt, when emerging from the square, to be positively giddy. Taking down these lamps, like putting them up, has been no easy job. The crown of lights, which was daily lowered for recarboning, was quite a massive piece of ironwork, and the pole itself was so heavy that it had to be sawn into three pieces for taking down. I am afraid that we have about seen the last of "high lights" in this city.

Speaking of poles reminds me that the Subway Board also has this subject on its mind. The United States Illuminating Company has succeeded in obtaining a preliminary injunction from one of the Courts restraining the Board from removing its poles and wires, and from doing any acts tending to give the Metropolitan Telephone Company and the Western Union Telegraph Company, or the East River Electric Light Company, any greater facilities or privileges than it grants to the United States Company. The Subway Board were, however, a little too smart for the company, as they had managed the same day to strip off and carry away no fewer than four large cartloads of condemned wires belonging to the company. This fight has to be settled sooner or later, and now that the Board has the sympathy and support of the powers municipal, it is not improbable that the companies in opposition may suffer defeat. It cannot be said that the subways are yet in a satisfactory condition, and evidence of this fact is afforded in the permission granted to the Western Union Company to string four 50-wire cables along Broadway and Park Row until the subways of that neighbourhood are repaired and ready.

On the invitation of General Alexander Webb, President of the College of the City of New York, a meeting of the American Institute of Electrical Engineers was held this week at the College, when a Paper was read by Prof. W. H. Geyer, of the Stevens Institute of Technology, on "The Geyer-Bristol Meter for Direct and Alternating Currents." This meter is based on the principle of the unequal heating of portions of the same circuit having the same sectional area, but differing in shape, so that one presents a greater radiating surface than the other. I have already referred to this invention some time back. M. Abdank-Abakanowicz then read a very interesting little Paper on some theoretical considerations with respect to the Abdank magnetic call, and exhibited his integraph, as well as the Carpentier melotrope and electric recording apparatus for music. Through the kindness of Prof. R. Ogden Doremus, who is well known to many of your readers, the electrical and chemical departments of the college were thrown open to the inspection of the members. I may mention that M. Abdank, who contributed so much to the business of the evening, and who was exceedingly well received, is in this country at present representing the electrical departments of the approaching Paris Exposition. It is understood that he has been very successful, and that the advances made by electricity in America will be illustrated in a series of magnificent exhibits. You may safely count on seeing a good many American electricians on your side of the ocean next year.

An instructive Paper on lightning was read this week before the New York Electric Club by Dr. M. G. Parker, of Lowell, Mass. Dr. Parker, who is an enthusiastic amateur, followed in general the lines of the recent report of the Meteorological Society; but he gave as his own contribution to the study a number of observations tending to prove that the flashes of lightning have a definite rotary motion, turning upon themselves, so to speak, as they go. Some of the motions are twisted, resembling a loosely twisted rope which twists both ways. The curl of motion resembled a twisted ribbon, for example, or a shaving from a carpenter's plane, and was generally from left to right. The Paper was illustrated by some beautiful photographs of lightning.

CORRESPONDENCE.

MR. SPRAGUE ON ELECTRIC MOTORS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I note in your edition of last week a reply, by Mr. F. J. Sprague, to my criticism on the Richmond motor curves. Your readers will recollect that in my Paper I published, for the first time I believe, a method of analysing the action of electric motors by means of three variables, the determination of which depended on brake tests. I further showed by curves, taken from different types of machines, the errors likely to result from the use of electrical measurements only.

The Sprague curves I maintained were plotted from calculations based solely on electrical data. The superiority of my method seems so obvious that further discussion is unnecessary; in fact, Mr. Sprague admits the advantages to be gained by the use of brake tests as indicated in my Paper. There are, however, a few misstatements in the reply which I will briefly mention. Mr. Sprague gives three curves referring to one of his stock motors. The first he calls the "Sprague curve." It is presumably calculated from electrical data. The second he calls the "actual curve." I assume this to be obtained by a brake test. The third he calls "Snell's curve." How he obtained the figures of this I know not. The curve, if made according to my method, would show the *actual connection between the variables, speed and current*. If this be correctly plotted from the brake test, then Mr. Sprague's *actual curve* is wrong. Perhaps the experimenter will explain the apparent discrepancy.

Mr. Sprague has further misquoted me with reference to the internal resistance of motors. My figures apply only to the motors, and not to any external resistance.

Perhaps the most interesting point of the reply is that relating to the starting of tram-motors. Mr. Sprague prefers to put the whole of his device in the motor itself. I, for small machines at any rate, would place it outside.

The external resistance may be compared to a *throttle valve*, which wiredraws the electricity, if I may be allowed such an expression. It is not a very efficient arrangement, I grant; but it has two practical advantages. Firstly, it is cheap and easy to keep in order; and, secondly, it spends the superfluous heat where the possible damage is a minimum.

Mr Sprague's device resembles to some extent an *expansion valve*, but the analogy is not very complete. It enables a small current, with many convolutions on the fields, to do the same work per revolution of the armature that a larger current could do with fewer turns. But since the value of the motor electromotive force, and much more so $\frac{\text{B.H.P.}746}{c}$, is much decreased, the speed is proportionately lowered, and with it the efficiency. In fact, I do not think there is much to choose between either method if efficiency be the only criterion. However, the cumulative field device has this serious drawback. To lessen the first rush of current, on making circuit, the ohmic resistance of the motor must be considerable. This implies an extra outlay in the copper for windings. Also, since the total heat waste is confined to the motor, the risk of breakdowns would appear to be increased. In large motors, say 15 or 20 horse-power and upwards, the conditions are somewhat altered. The magnets are usually so massive, and the characteristic so straight, that there is plenty of margin for some cumulative coils up to, say, that point where the characteristic is decidedly flat. The motor should not be expected to work beyond this part of the characteristic, for the efficiency falls so rapidly when this point is passed. I would, therefore, use an external resistance up to the flat part of the curve, and then vary the windings if further regulation were required. This latter arrangement corresponds approximately to the expansion lever and regulator of a steam locomotive, where on starting the lever is put in full gear, and the regulator opened slowly, so as to overcome the inertia of the load without undue shock or strain; then having acquired a certain velocity the lever is notched up to suit the conditions obtaining.

I think that most engineers will admit the justice of my mechanical parallel.

Digitized by Google

The figures for shunt motors quoted by Mr. Sprague are decidedly good, and agree well with English practice.

Concluding, I would thank Mr. Sprague for the information he has given us of American motors. I also assure him that English engineers are looking as eagerly as their American cousins for the success of electric traction in the United States, where circumstances have hitherto favoured the enterprise.

Progress reported from across the Atlantic is always welcome, for it means as much solid gain to the whole industry as though it were in London itself. May I venture to hope that Mr. Sprague will shortly favour us with curves of his latest machines, embodying both his and my own method of treatment.—Yours, &c., ALBION T. SNELL.

THE STANDARD CONDUCTIVITY OF COPPER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Your correspondent "Megohm," in your last week's issue, expresses surprise at 102 per cent. being considered quite an ordinary conductivity for copper.

The lines of this Company, some of which have withstood the storms and smoke of fifteen years, are principally of copper having a conductivity of from 100 to a little over 102 per cent.

A sample of this copper, which I gave to Dr. Muirhead about twelve years ago, caused that gentleman, after testing it, to say that the standard would have to be altered.—Yours, &c.,

F. HIGGINS.

The Exchange Telegraph Company (Limited),
17 and 18, Cornhill, E.C., 23rd November, 1888.

GLOBULAR LIGHTNING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Referring to the letter on the above subject in your issue of the 16th inst., the following facts, of which I have had experience, I think would be of interest to your readers.

During a very heavy thunderstorm a very powerful charge entered a cabin and completely destroyed a telegraph instrument there, and in passing to earth (which was taken from the rails) took the form of a very vivid globe of fire, which appeared to be about 18in. in diameter. Part of this same charge travelled the line for 1½ miles, doing slight damage on its way, and went to earth in a very peculiar manner. It fused the binding of the saddle wire, destroyed the roof, split the pole down about 9in., and at this point caught the lightning conductor, which was also used as a "feeder" for the arms, and fused the parts next to the soldered joints (passing over the solder), went on till it came in contact with the stay wires, at which it went to earth. But in passing to earth at this point the charge seemed to be so great that the wire could not contain it. A "sleeper" near which it passed was completely shattered. The great vibrations which were caused by this tumbled several workmen who were near at the time.—Yours, &c., J. H.

Kilmarnock, November 23, 1888.

THE FIRST TELEPHONE CALL OFFICE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have observed the correspondence which has been going on in your columns with reference to the date at which the first telephone call office was opened in this country, and as I have been referred to as the authority for a certain date, perhaps I may be allowed to say a word.

The call office at Hall's, the cabman's, in Edinburgh, was not opened by the National Company, but by its predecessor, the Scottish Telephonic Exchange, my connection with which began, I find, in January, 1880. The exact date of the opening of this call office it may not now be easy to discover, but I know that it was shortly after the date I have named. In any case the call office in the Temple, opened, Mr. Munro says, in April, 1880, must have run it hard for priority if it did not precede it.

But however important this question of dates may be as an abstract inquiry, it seems to me that credit belongs not so much to those first in the field as to those who have followed the matter up so as to make call offices of practical utility. Mr. Munro may secure for the United Company the credit of being the pioneers. In precisely the same measure will be their discredit for having abandoned their early policy, for it is well known that at whatever date their call offices were originally opened, they were shortly afterwards closed to the public, and have only within the last few months been reopened as the result of pressure brought to bear upon the directors from outside. The managing director, Mr. Morgan, is even now opposed to their use.—Yours, &c., F. FAITHFULL BEGG.

6, Draper's-gardens, E.C., 26th Nov., 1888.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In thanking Mr. Munro for the information he so kindly gives, I will merely point out that I have sustained my objection to the statement in his article that the first *public* call offices were established in London. He now says that the first public offices were opened there in August, 1881, although a room for the use of the legal fraternity was established in the Temple in 1880. The latter cannot be counted, as it was for the legal profession only, consequently was not *public*. The call offices which I have shown were opened in Edinburgh in 1880 were for *general*, *i.e.*, public use. That they were opened by the Scottish Telephone Company (Limited) does not affect the question. I am not contending for the National Company or any other, but for historic truth.—Yours, &c.,

November 27, 1888. A. S. T. E. and E.

THE DEATH OF M. LUCIEN GAULARD.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have the painful duty to inform you of the death of Lucien Gaulard, electrical engineer, who died yesterday at St. Anne Madhouse, broken-hearted, a victim of science and of his own great genius.

I enclose a letter in French, which I have this day sent to the electrical papers here, and I thought that perhaps you would not mind associating yourself and your paper in the expression of universal regret that this sad death must arouse in all generous hearts and all lovers of science.

Whatever can be said, Lucien Gaulard will go to posterity as the first one (to say the least) who invented the practical way of transmitting the electrical current at great distances. Look to every part of the world, the great impetus, the immense projects of central stations of the greatest magnitude. To whom primarily do we owe all this? Lucien Gaulard.

I am sure that the greater portion of your numerous readers, and the great mass of the English nation, always ready to be fair and honour real worth, from wherever it comes and wherever it goes, will associate themselves readily and spontaneously, and share with us French electricians the great loss we have sustained by the death of Lucien Gaulard, and will give his widow this supreme satisfaction in the midst of her grief—that they honour the memory and genius of her departed and unrewarded husband.—Yours, &c., E. H. CADIOT.

Paris, November 27, 1888.

M. Faure's New Secondary Battery.—In M. Faure's new secondary battery the plates are of copper and zinc. The metals are taken in a finely divided state, and are then compressed into plates and enclosed by a diaphragm or septum of prepared asbestos. The electrolyte is a solution of phosphate of potash. During the process of formation the phosphate of potash is decomposed, forming insoluble phosphate of copper on the surface of the copper plate. When the electrolyte is exhausted, a fresh solution of phosphate of potash is put in, and the cell is ready for use. The phosphate of copper is decomposed on discharging, and phosphate of zinc is formed on the zinc plate. On charging the reverse process takes place. The diaphragm consists of sheets of asbestos ·8 millimetres thick. These sheets are dipped into a solution of chloride of calcium or chloride of barium; they are then dried, and afterwards dipped into a solution of soluble silicate, such as the silicate of soda or a fluosilicate, which is capable of forming an insoluble compound with the first salt.

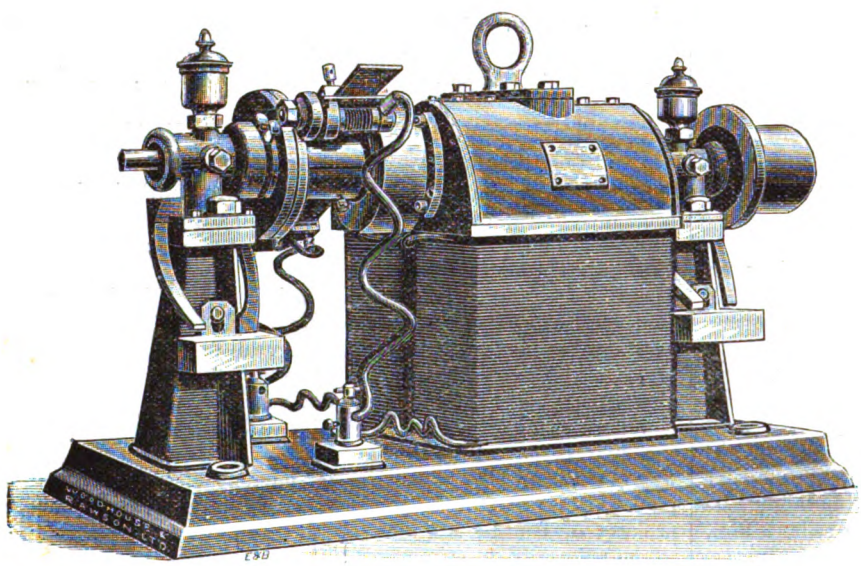
THE WOODHOUSE AND RAWSON DYNAMO.

Our illustration represents the "W and R Dynamo, Type H," which is now being made by Messrs. Woodhouse and Rawson especially for electrolytic work.

It is a substantial and strongly-built machine, having an armature of the shuttle type, and shunt-wound magnets. The makers claim that it is very suitable for use by unskilled persons, as it is not easily damaged by rough handling and requires very little attention. The machine can be wound to any desired voltage between 10 and 200 volts, with an approximately proportional variation in the current output. The following are sizes generally supplied :—

Approx. revs. per min.	Amperes.	Volts.	Watts.
1,500	25	25	625
1,500	12	50	600
2,000	25	40	1,000
2,000	20	50	1,000
2,000	12	80	960
2,000	10	100	1,000

Extreme length over pulley.	Extreme height.	Extreme width.	Diam. of pulley.
2ft. 2½in.	1ft. 4½in.	12½in.	3½in.



The Woodhouse and Rawson Dynamo.

We may mention that Messrs. Woodhouse and Rawson recently supplied twenty-eight of these dynamos on one order from Messrs. Johnson and Sons, of Cross-street, Finsbury, where they are giving every satisfaction.

COMPANIES' MEETINGS.

Crompton and Co. (Limited).

The first ordinary general meeting of the shareholders of this Company was held yesterday (Thursday), at the Cannon-street Hotel, under the presidency of the Right Hon. Viscount Torrington.

The SECRETARY (Mr. Francis Reeves) having read the notice calling the meeting,

The CHAIRMAN stated: Doubtless many of the shareholders were surprised at receiving notice of this meeting so soon after the public issue of the prospectus, but the fact is that the Company was registered on the 30th July last, and, consequently, this meeting had to be convened in compliance with the Act of Parliament. There is no paper of business to lay before the shareholders; indeed, there appears little to be done on these occasions but for the Directors to tell the members anything they may think interesting as to the value of the property they have purchased and the probabilities of its being a successful business. In this case, however, there can be little to add to the statements made in the prospectus, advertised only three weeks ago; but the Directors have been in office long enough to make themselves acquainted fully with the business and to satisfy themselves that the Company have acquired a valuable property. It would be unwise at what is practically a public meeting to give details of the contracts which are in negotiation or of the orders in hand. It may be stated, however, that orders have been taken for a complete installation of electric plant sufficient for 2,000 lights for a Supply Company for one of our provincial towns, also one for a Continental town, and two large installations for docks, besides a quantity of machinery and plant for the Kensington and Knightsbridge Electric Lighting Company, which company have so well served their customers—there having been no failure of the light since they started some two years ago—that they have orders coming in really faster than they can execute them. It is now a well-ascertained and proved fact that electric lighting can be made to pay, and, indeed, to pay well, if only the supply be to a sufficiently large number of consumers, and as a consequence of this knowledge, Electric Supply Companies have been started in many places. Each of these companies will require electrical machinery, fittings, and instruments, some of the orders for which will almost undoubtedly come to this Company. In addition to the employment of electricity for lighting purposes, it is admirably adapted for motive-power. Quite recently an electric crane has been constructed at the works for a firm of large London manufacturers. By means of such cranes, builders will get rid of the necessity of placing a steam engine, as is now done, at the top of high scaffoldingt—he power will in future be generated below and carried up to the crane by means of a small wire. The crane in question has been in successful use for about two months, and gives great satisfaction. Further orders for this class of work are expected. Various other negotiations are in progress for central station lighting, but these are not sufficiently advanced to admit of their being confidently announced to the shareholders. The Directors, however, are hopeful shortly to report something more definite on this subject. The Arc Works at Chelmsford are in good order, and with the few additions now being made to them are sufficiently large and complete to meet the additional orders which the increased working capital is expected to bring. The management of the Company's business is well placed in the hands of Messrs. Crompton and Albright, two gentlemen who owe their position in the electrical world entirely to their professional skill, integrity, and untiring perseverance. They have shown their confidence in the Company by reinvesting £25,000 of their purchase-money in Preference Shares, in addition to their £40,000 of Ordinary Shares, which are paid to them as part of their purchase money. Thus the Company have every security that these gentlemen, who are so very largely interested in the business, will do their utmost to make it successful. The Directors hope to be able to declare an interim dividend in the month of January next, and at the same time propose to pay the interest to those who have paid up in full on their shares. I regret to say that Mr. Crompton has gone to Vienna to arrange some matters with the Imperial Continental Gas Association, and is now in Berlin, where he hopes to make some important arrangements for the benefit of the Company. I have nothing further to add to that statement. If there are any shareholders present who wish to ask any questions in connection with the Company, I shall be very happy to answer them.

The Hon. EVELYN PIERPONT quoted a passage from the prospectus, and asked how the dividends were payable on the Preference and the Ordinary shares.

The SECRETARY replied that after 7 per cent. had been paid to the Preference shareholders, and an amount equal to that amount paid to the Ordinary shareholders, supposing the whole capital were called up and £7,000 were required to pay 7 per cent. on £100,000, then the next £7,000 would be paid to the Ordinary shareholders.

Mr. PIERPONT: Then before the Preference shareholders get anything beyond 7 per cent. those holding Ordinary shares will get about 17 per cent. ?

The SECRETARY: Yes, that is so.

The CHAIRMAN inquired if the point were understood now.

Mr. PIERPONT said that he understood the point now, but he took it from the prospectus to mean that the Ordinary shareholders were to have 7 per cent., and then that the two classes would share alike.

Mr. HODGE asked for some information respecting the subsequent agreement that had been made with respect to the payment of interest to Messrs. Crompton from the date at which the income had been assigned to the Company.

The SECRETARY said that the Company took the benefit of all the profits from the concern from the 31st of March—that was to say, from the date the Company took all the profits. He added that they would be paid their dividend on the amounts paid up, and reckoning from the dates at which they were paid up.

Mr. HODGE thought there was no advantage to the shareholders in having had the profits handed over as from the 31st of March.

The SECRETARY said that there was an undoubted advantage, and that it made the 7 per cent. on the Ordinary shares safe for this year at all events.

Mr. HODGE, continuing, said it was stated in the circular that the income of the Company would be assigned to the new company as from the end of March, but now, owing to this recent arrangement, that had been completely altered, and altered, he maintained, to the prejudice of the shareholders, because, whereas had the first arrangement stood good, the shareholders would have been entitled to a dividend on the shares they held now. Messrs. Crompton would take possession of the sum that had

Digitized by Google

accrued, and the shareholders would only have interest on their shares at the rate of 7 per cent., as the instalments were paid up.

The SECRETARY: There has been practically no alteration. The original agreement provided for the payment of interest on the amounts owing to Messrs. R. E. Crompton on the purchase. The amended agreement merely states the date from which that interest is to be paid. As we take all the profits from the 31st March Messrs. Crompton could hardly be expected to give up those profits for three months without some consideration, and we agreed to pay them 5 per cent. on the amounts owed to them. With regard to Mr. Pierpont's question, the Articles of Association were quite clear on the matter of the division of the profits. [He quoted the clause bearing on the subject.]

Mr. PIERPONT thought that the wording of the prospectus was a little ambiguous.

The CHAIRMAN; It is very difficult to word things so that every one can understand them, but the clause which the secretary has read out is very clear.

A vote of thanks was passed to the Chairman and the proceedings terminated.

Filsen-Joel and General Electric Light Company (Limited).

The seventh ordinary general meeting of the shareholders of this Company was held at the Cannon-street Hotel, on the 23rd inst., under the presidency of Sir Rawson W. Rawson, K.C.M.G., C.B.

The SECRETARY (Mr. W. H. Trentham) having read the notice calling the meeting,

The CHAIRMAN said: This is our annual meeting, ladies and gentlemen, and the Directors have thought it a suitable opportunity for bringing before you the state of affairs as they exist at the present moment, with a review of what has taken place during the present year since the important meeting in March last, and we have thought it desirable in our report to invite an expression of your views and wishes as regards the future operations of the Company. We, the Directors, expressed our opinion on the subject last March, but our views did not meet with support, the majority being a sufficiently large body of the shareholders, and my colleagues were reappointed and were instructed to make provision for the sale of the business. I merely briefly review this, which is stated in the report. We did our best to obtain an offer for the business. That offer was brought to your notice, and although it was a small one it was considered under the circumstances that it would be advisable to accept it, and the shareholders did accept it. However, an obstacle was placed in the way of carrying out the sale, and we brought the matter again before the shareholders. One or more of them at that meeting were of opinion that, if a limited time were allowed, an opportunity would present itself of obtaining some satisfactory offer superior to that made by the proposed purchaser. The Directors then determined that they would allow until the general meeting for any shareholders to make such a proposal; and none having presented itself as the time approached for this, our appointed annual meeting, we prepared a report, stating the circumstances, and laying before the shareholders the position in which we were placed. Our recommendation was not approved. The arrangement that we had proposed, in accordance with the express wishes of the shareholders, was not approved, or was stopped and thrown over, and now the time has come for something to be done. We have received two communications from shareholders, one of them being from Mr. Roper, stating that it is his intention at the present meeting to propose steps for the voluntary liquidation of the Company; and the other is from Mr. Fellowes, who comments in detail on the transactions of the past year—which is not exactly the question before us—but who makes no definite proposal. He says it is the Directors' business to make a proposal. But we have done so, and you have not accepted it; we adopted your wishes, and we were not able to carry them out. We gave the shareholder, who thought he could obtain an offer, more than the two months mentioned at the last meeting. But no offer has presented itself, and now, as the Board state in the report, having explained the position, we feel that it rests with the shareholders to furnish an indication of their wishes. It will be my duty to place before you the definite proposal which has been sent in by one of your body. The order of our proceedings, however, is first to move the adoption of this report and accounts, and the first resolution which I now propose is—

"That the report of the Directors, dated the 10th November, 1888, together with the accounts and balance-sheet for the year ended June 30th, be received and adopted."

Mr HORACE W. SCRIVEN seconded the motion.

Mr. GEORGE HOPKINS asked for some further information regarding the accounts, observing that nearly £3,000 worth of Consols and £3,672 had been received in Stocks. The indebtedness of the Company on the 30th of June, as compared with the 30th June, 1887, had increased by £740, making a total of about £7,400; and, looking through the accounts, he was at a loss to see where all that money had gone to. He noticed that £1,307 had been put down as general factory charges, and in looking through former accounts, as far as he could see that was the first time that that item had appeared, and he wished for some explanation of the matter. He really could not understand what they had spent £300 on law charges for. He thought the meeting was held unduly late—five months after the date at which the accounts had been presented—and he wished to know what the general financial position of the Company was at the present time.

The CHAIRMAN stated that they had not expected to hold the meeting at all. The sale of their business had been proposed to be carried out on the 26th July, and they did not proceed to the audit of the accounts until they were forced to do it by the rejection of that sale.

Mr. HOPKINS: But your previous general meeting was in Nov., 1877.

Mr. FELLOWES read a long letter which he had addressed to the Directors on the position, financial and otherwise, of the Company. He dissented from the proposal referred to in the report in writing down the goodwill and patent rights for £25,000 to a nominal amount, holding that, in the hands of good business men, that item might be of even greater value than £25,000, and that the Directors could divide any profit that might be made, whatever the amount of goodwill and patent rights were valued at. He wished to know whether the expenses of the Company could not be materially reduced, arguing that they could be, and holding that it was for the Directors to say whether the Company could be carried on profitably; and if, in their opinion, it could be, then to state the grounds on which it could be. He did not think that a resolution for winding up the Company ought to be proposed before the shareholders had had submitted to them a full statement of the actual position of the Company.

A SHAREHOLDER asked the position of the litigation between Mr. Fyfe, the Company, and Mr. Gwynne.

The CHAIRMAN replied that Mr. Fyfe brought an action during the vacation to restrain the sale to which he (the Chairman) had referred. The Judge thought there was a sufficient ground for placing such an amount of obstacle in the way of carrying it out, or of carrying on the business without it, that it was in the interests of the Company to profit by Mr. Gwynne's willingness to withdraw his offer. The sale having dropped, the Directors knew nothing more except that the Company would have to pay another large bill for costs in the matter of Mr. Fyfe's action.

Mr. QUILTER, M.P., said that he was a large shareholder, and that he represented Mr. Charles Morrison and other large shareholders. He reminded the Directors that ever since he and his friends had been shareholders in the Company they had loyally supported whatever the Directors had brought forward, and that they had abstained from any agitation that had been going on respecting the affairs of the Company. Considering all the circumstances, he and his friends did not intend that the Company should go on as it had gone on, losing money and coming upon the shareholders for fresh funds. They did not believe that the Company could be successfully carried on, and he was sure that there were many shareholders in the Company who could ill afford to support the constant drains which had been made upon them, and apparently for no good purpose whatever. He thought it would be most conducive to the interests of the shareholders that the Company should be wound up, and that they should get out of a very bad bargain, and if it were not decided to liquidate the Company voluntarily, they would take steps to get it wound up forthwith compulsorily.

Mr. SCRIVEN, in answer to Mr. Hopkins, stated that the Directors had not thought it necessary to have another special balance sheet made up to date. Comparing the present with the previous balance sheet, they had called up £3,069 more capital, and they had increased their liabilities by £739. They had also a decrease in cash of £2,063. On that side of the account, therefore, they were £5,861 worse off. But on the other side of the account they had increased the stock, which had been very fairly valued, to the extent of £3,805, and they had increased the book debts by £666. There was a balance loss shown of £734, and there was a dividend paid since the previous balance sheet of £400. That made the figures very nearly balance. The item of £1,307 for general factory charges he was responsible for, it having been his wish to show the shareholders what they might expect the general annual charges to be if it were decided to continue the business. The item had been included in the expenditure previously in another way. Most of the remarks which had fallen from Mr. Fellowes and Mr. Quilter referred to a proposal that would come before the meeting after the adoption of the report. Mr. Fellowes wanted the Directors to make a proposal, but they had done so. Last March they stated that by the expenditure of further capital, and writing down the present capital, a large profit could be made—not from figures that could be shown, but from the future of electricity. He still entertained that opinion, and he believed that if the shareholders worked with the Directors, and the latter had the confidence of the shareholders, now was the time when electricity could be made to pay.

The CHAIRMAN stated that Mr. Fellowes had said that they could divide their profit, notwithstanding the £25,000 standing in the balance-sheet for goodwill and patent rights; but their legal advisers took a different view, and he thought the shareholders would agree that the Directors ought to be guided by the legal advisers of the Company. He then put the resolution, and declared it carried.

On the motion of Mr. SCRIVEN, seconded by Mr. G. L. WHATELEY, Sir Rawson W. Rawson was re-elected a Director of the Company, and the auditors, Messrs. Hays, Akers and Hays, were reappointed on the motion of Mr. HOPKINS, seconded by Mr. QUILTER.

Mr. ROPER stated that the proposal which he wished to make was in accordance with what was set out by the Directors in their report. He believed that they could not continue working, for the reason that "a house divided against itself cannot stand." Therefore, as they had to fall, they had better fall as decently as they could. It was infinitely better that the Company should be wound up voluntarily, as Mr. Quilter had said, for whatever might come back to the shareholders by a voluntary liquidation, if there was a compulsory liquidation they would never see a farthing, and probably they would have to pay up a large amount of the uncalled capital. He therefore proposed—

"That the Directors be requested to take the necessary steps for the voluntary liquidation of the Company."

Mr. QUILTER seconded the motion.

Mr. FELLOWES expressed his opinion that it was not competent for the meeting to pass a resolution winding up the Company, although it might be competent for the Directors to receive an intimation on that matter, in which case a fresh meeting to consider the subject would have to be called.

The CHAIRMAN pointed out that the resolution was not for winding up the Company, but requesting the Directors to take the necessary steps

Digitized by Google

with that object, and, of course, the matter would be brought before the shareholders.

Mr. FELLOWES asked whether it was competent for the meeting to consider the question at all.

The SOLICITOR (Mr. Parker) said it was perfectly competent for the meeting to pass the resolution proposed by Mr. Roper. It would then be the duty of the Directors to call another meeting for passing a resolution voluntarily winding up the Company.

Mr. GWYNNE said that he was by far the largest shareholder in the Company, and, under the circumstances, he had come to the same conclusion that Mr. Quilter and that gentleman's friends had come to, that the continuation of the Company in its present divided state was impossible.

Mr. WHATELEY said that the Articles of Association were very stringent, and no business could be brought before a meeting without notice. He therefore suggested that Mr. Roper's resolution should be put as a recommendation to the Directors.

After some further discussion, and the Directors having expressed their views as to the position of the Company, and the best course to be taken under the circumstances, Mr. Whateley's suggestion was acted upon, and the resolution was passed in the form of a recommendation to the Directors.

The CHAIRMAN, in answer to Mr. HOPKINS, pointed out that only £12,000 of the capital remained uncalled, and that the existing contracts were only for one year.

A vote of thanks to the Chairman and Directors brought the proceedings to a close.

Blackpool Electric Tramway Company (Limited).

At the meeting of this Company, held on Saturday last, the following report of the Directors was presented to the shareholders:—

The revenue account shows a balance in hand for the year of £1,834 10s. 9d. Adding to this £22. 19s. 6½d. from last year makes an available amount of £1,857. 10s. 3½d., of which the Directors recommend the following disposal:—

	£	s.	d.
Dividend of 4 per cent. on the paid-up share capital	801	0	0
Depreciation and reserve fund	1,000	0	0
Balance to next year's account	56	10	3½
	£1,857	10	3½

The depreciation and reserve fund, with the addition of £1,000 as above recommended, will be £2,159. The number of passengers carried this year was 711,218, against 618,527 last year. The number of miles run during the year was about 90,000. The retiring directors are Messrs. Horsfall, Bickerstaffe, and Broadbent, who are eligible for re-election. The Board regret to have to record the retirement during the year from the directorate of their esteemed colleague, Mr. Joseph Moseley. Mr. Broadbent's services as Managing Director have been secured again for the coming year.

At this meeting the CHAIRMAN moved the adoption of the statement of accounts and Directors' report. He said: Had they taken less for depreciation, and so made the dividend 5 per cent., there would have been a less dividend next year. The working expenses had been reduced this year something like £500. Last year they were £4,291, this year £3,793. On the other hand the receipts last year were £4,406, this year £5,443, showing that whilst there had been economy in the working, the traffic had so increased that they had now got into a sound position. The machinery was equal to, if not better than, it was a year ago. The line was in good working order, and he thought there was every prospect of a good future. It was also satisfactory to know that although there had been many electric tramways at Brussels, in America, and other places, he believed that there were none, taken altogether, so efficient as the tramway at Blackpool. Working trams by accumulators, electric engines, and other modes, had been tried, but so far the difficulty with them had been the carrying of the dead weight. It might be said this Company had gone to great expense in the formation of its plant, and that was true. No doubt material could be obtained at less cost now, for science and other things had developed of late, but he believed Mr. Smith's electric tramway was the best of anything of the kind in existence at the present time. He then moved the adoption of the report and balance-sheet.

Mr. HOYLE seconded. He mentioned the existence of verdigris upon some of the copper rods, and also thought enough account had not been taken of the property of the metal to contract and expand with the changes in the weather.

The CHAIRMAN explained that as last year only £400 was put to the reserve fund, instead of £700, the amount was made up this year, this being a good season.

The motion was unanimously agreed to.

The retiring Directors, Messrs. Richard Horsfall, John Bickerstaffe and James Broadbent, were then re-elected.

Mr. HOYLE, in seconding the motion for the re-election of the retiring Directors, called attention to the Sunday question. He was informed that if they were to run three months in the year on Sundays in the season they would clear all expenses. He did not see why they should not work on Sundays for three months, nor what harm there was in it.

After some remarks in reply from the Chairman, a vote of thanks brought the meeting to a conclusion.

The Maxim-Weston Electric Company (Limited).

Notice has been given that an extraordinary general meeting of the Maxim-Weston Electric Company (Limited) will be held at the Cannon-street Hotel, in the City of London, on Monday, the 3rd day of December, 1888, at 12 o'clock at noon, when the following resolutions will be submitted as special resolutions:—

1. *That the Maxim-Weston Electric Company (Limited) be wound up voluntarily, and that Mr. John Marks, of 114, Great Russell-street, W.C., Mr. J. M. Klenck, 42, Bishopsgate-street Within, E.C., and Mr. Louis Sealy, of 23, Churchfield-road, Ealing, be and they are hereby appointed liquidators for the purpose of such winding up.*

2. *That the liquidators be and they are hereby authorised to sell and transfer, subject to due provision being made for dissentient shareholders (if any) all the letters patent, business, property, machinery, plant, assets and effects of the company, whatsoever and wheresoever, to a company to be formed with limited liability, under the Companies' Acts, 1862 to 1886, with a capital not exceeding £75,000 divided into 500,000 shares of three shillings each, for the purpose, amongst other things, of taking over and working the property of this company upon the following terms:—(a.) The new company shall pay and discharge the debts and liabilities of this company, and also the expenses of and incident to the winding up of the same, and of the incorporation of the new company, and of the sale and transfer by the liquidators of the assets and liabilities of the company to the new company. (b.) The new company shall allot and issue to the liquidators, or as they shall direct, 312,000 shares in the new company of three shillings each, upon each of which there shall be credited the sum of two shillings, a proper agreement being filed with the Registrar of Joint Stock Companies before the issue of such shares, so that the same may be liable to the payment of one shilling per share and no more.*

3. *That the liquidators be and they are hereby authorised and directed to procure to be allotted to every member of this company requiring the same one share in the new company, with two shillings credited as paid thereon, for and in respect of every share held by him in this company; provided always that, to entitle the members of this company to an allotment of*

such new shares, applications must be made for the same in writing within ten days after the posting of a notice informing him of his right to apply for the same, addressed to his registered address in the books of the company. If no such application is received by the liquidators within the time limited as aforesaid, the right of such members to receive such proportion of shares shall be absolutely at an end, and the liquidators, in order that the necessary capital may be promptly raised, and the liquidation closed, shall dispose of any shares refused or not applied for as aforesaid to any person or persons whether shareholders or not, at such price (if any) and upon such terms as the liquidators may think fit.

4. *That the liquidators be, and they are hereby authorised to continue the business of the company pending the transfer thereof to the new company, and to consent to the registration of the new company by the same or a similar name to that of the company.*

NEW COMPANIES REGISTERED.

MINING AND GENERAL ELECTRIC LAMP COMPANY.—This company has been formed, with a capital of £100,000 in £1 shares, for the purpose of acquiring from the New Portable Electric Lamp and Power Syndicate Company (Limited), their patents and system for the manufacture of an electric miners' lamp, a lamp for the electric lighting of railway carriages, a lamp for domestic purposes, and for use in factories and places where a portable and absolutely safe light is required. The price to be paid for all the patents is £80,000, payable as to £46,000 in cash, £20,000 in fully-paid shares, and the balance, at the option of the directors, in cash or fully-paid shares. Basing a calculation on an estimated annual sale of only 80,000 lamps amongst all the collieries, factories, and railway companies of the United Kingdom (including in this estimate the foreign user of the patents as well), it is stated that a profit of 15 per cent. per annum on the capital of the company would be forthcoming. Three of the directors are Fellows of the Royal Society, and the Earl of Crawford was on the Royal Commission of Mines. Mr. Higson, the consulting engineer, is one of the largest colliery managers, and the managing director of the Ebbw Vale Steel Company.

The company is registered by Paine, Son and Pollock, 14, St. Helens-place, E.C., and the first subscribers are :—

	Shares.
F. H. Sumner, 17, Queen Anne's-gate, Westminster	1
B. Nicholson, The Torrs, South Norwood-park, S.E.	1
J. Wood, 16, Matham-grove, East Dulwich, S.E.	1
H. W. Roach, 33, Warlingham-road, Goose Green, S.E.	1
G. C. Holman, 104, Fort-road, Bermondsey	1
E. W. Francis, 38, Kimberley-road, Clapham-rise, S.W.	1
H. A., 90, Royal-road, Kennington-park, S.E.	1

There shall not be less than three nor more than seven directors of the company. Each director shall hold not less than 500 shares in the company. The directors by way of remuneration for their services shall be paid out of the funds of the company the sum of £2,000 per annum.

SUNGEI UJONG (MALAY PENINSULA) RAILWAY COMPANY (LIMITED). Registered by Ashurst, Morris, Crisp and Co., 6, Old Jewry, E.C., with a capital of £75,000, in shares of £10 each. Object, to enter into and carry into effect an agreement made between Thomas Heslop Hill and Ambrose Beatty Rathbone of the one part, and the company of the other part, to construct or acquire, and equip, maintain, and work railways, tramways, lines of telegraph and telephones, or other means of communication or appliances of a similar nature in the Malay Peninsula, and for the above purposes to enter into and carry into effect any contracts, and apply for, accept and carry into effect such concessions or authorities as may be deemed necessary or desirable. The first subscribers are :—

	Shares.
W. Marshall, 280, Devonshire-road, S.E.	1
A. Mitchell, 287, City-road, E.C.	1
J. Gates, 61, South-hill-park, Hampstead	1
S. Crouch, 173, Isledon-road, N.	1
E. Disney, Steele-road, Sydenham	1
E. T. Botwright, 23, Sutton-place, Hackney	1
T. Nettleship, 1, Mildmay-park, N.	1

The number of directors shall not be less than three nor more than seven, and the first shall be appointed by the signatories to the Memorandum of Association. The qualification of a director shall be the holding in his own right of shares or debentures or debenture stock in the company of the nominal value of £500. The directors shall be entitled to receive out of the funds of the company by way of remuneration, from the date of the appointment of the first directors, £500 per annum, so long as their number shall not exceed three, and £150 additional for every further director up to five.

WINDSOR AND ETON ELECTRIC LIGHT COMPANY (LIMITED).—Registered by Sydney Morse, 7, Fenchurch-avenue, E.C., with a capital of £30,000, divided into shares of £1 each, 50 being founders' shares. Object, to carry on the business of electric engineers, electricians, engineers and contractors, manufacturers of electrical apparatus, and mechanical and chemical engineers, and of producing light, heat, sound, and power by electricity, galvanism, or magnetism. The first subscribers are :—

	Shares.
Major-General C. E. Webber, 17, Egerton-gardens, S.W.	1
E. S. Churchill, Castlemead, Windsor	1
A. Shipley, Datchet	1
A. W. Shipley, River Bank, Datchet	1
A. Fox, 49, High-street, Windsor	1
W. Sevenoaks, Acre House, Windsor	1
W. J. McCloskie, Peascod-street, Windsor	1

The number of directors shall not be less than three, nor more than seven, and the qualification of a director shall be the holding of at least 20 shares in the capital of the company. The remuneration of directors shall be voted in general meeting.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended November 23rd, 1888, amounted to £5,842.

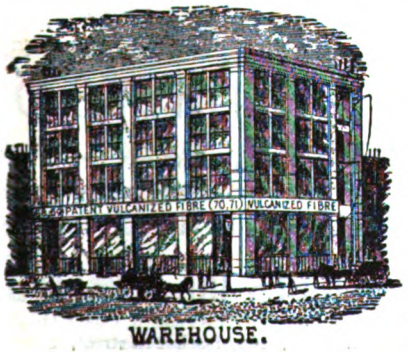
TELEGRAPH CONSTRUCTION AND MAINTENANCE COMPANY.—The directors of this company announce that they intend to replace the existing Six per Cent. Debentures, maturing on the 1st January, 1889, with Five per Cent. Debentures, to mature on the 1st January, 1894. Holders of the existing debentures can have them exchanged between the 15th and 31st of December. (Full particulars will be found in our advertisement column.)

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended November 23rd, 1888 (after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, Limited), were £4,938.

FOOTBALL.

PENZANCE V. PORTHCURNOW EXILES.—The advantages gained last year by the Eastern Telegraph Company's Porthcurnow staff (Exiles) over the Penzance Town Club had evidently placed the members of the latter upon their mettle, as the first match this year resulted in a decisive victory for the Town Club. On Wednesday, the 21st inst., the Penzance team journeyed to Porthcurnow to play the return match, and a good game was witnessed. The teams were evenly matched, and a very pleasant game was played, terminating in a win for Porthcurnow by five goals to four. Wind interfered with any long passing, and had it subsided a much faster game would have been witnessed. Teams :—Penzance—Kistler, goal ; Amor and Bodilly, backs ; Hocking, Stewart, and Sampson, half-backs ; Adson (captain), Walton, Baird, Peak, and Runnals, forwards. Porthcurnow Exiles—Martin, goal ; Milward and Hutchinson, backs ; Parker, Evans (captain), and King, half-backs ; Davenport, Roffey, E. Ash, Gordon, and Sweeting, forwards.

THE NON-CONDUCTOR OF ELECTRICITY.



WAREHOUSE.

VULCANISED FIBRE,

PATENTED.

This new material is supplied in two qualities, Flexible and Hard.

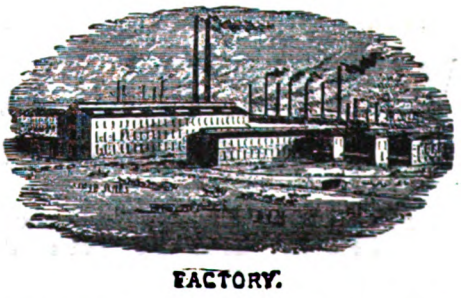
The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.



FACTORY.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 551.—Vol. XXII. FRIDAY, DECEMBER 7, 1888. Price 4d.

NOTES.

By a singular coincidence the change of title which the Society of Telegraph-Engineers is about to undergo is attended by a change in the character of the Council almost amounting to an entire exclusion of telegraphic representatives. Whether this feature of the list of candidates just issued by the Society in view of the election next Thursday is the result of accident, or, as our correspondent "Telegraphy" seems to suspect, of design, the incident is to be regretted as giving some colour to the complaints of those who have silently deprecated the disappearance of Telegraphy from the Society's official designation. We hope that these remarks and the publication of our correspondent's letter may, at any rate, have the desired effect on next year's nominations.

The *London Gazette* of this week contains the necessary statutory notices of the various Electric Lighting Companies which intend to apply to the Board of Trade for Provisional Orders under the Electric Lighting Acts of 1882 and 1888. The full list is given on another page. It will be seen that a very large portion of the metropolitan area has been scheduled. The limits extend as far as Hampstead in the North, and Streatham and Greenwich in the South, and may be said to comprise practically the whole of the City, the Central District, and the West End, and most of this area has been covered two or three times over. In a large number of cases the applications will be opposed by the local authorities. It is clear that the Board of Trade has no very easy task before it.

The Chelsea Vestry has declined to endorse the view that an Electric Lighting Order confers any monopoly upon the party to whom it is granted. At their last meeting, after listening to the remonstrances of a deputation from the Chelsea Electric Supply Company, they proceeded to pass resolutions acceding to the requests both of the London Electric Supply Company and of the Cadogan Company to be permitted to lay underground wires within the scheduled districts. The Chelsea Company will no doubt appeal to the Board of Trade, and if an authoritative decision is soon obtained it will not be a matter for regret that this question has assumed an acute form at a comparatively early stage.

At Ipswich another question of not less interest has arisen in connection with the working of the Act. Here, Messrs. Laurence, Paris and Scott, the well-known electrical engineers, have a central station scheme in hand, towards which both the local authorities and the majority of the inhabitants of the town appear to be thoroughly well disposed. Under these circumstances it was hoped that the project could be carried through without legislative sanction. Application was, therefore, recently made to the Town Council for permission to lay underground wires, but, although no opposition was raised, the Town Clerk gave it as his opinion that the Council possessed no authority to give the required permission in the absence of a Provisional Order or a License from the Board of Trade. The matter was, therefore, referred to the Board, in order to ascertain whether their intervention was necessary. At the last sitting of the Council a letter was read from Messrs. Paris and Scott asking permission to erect overhead wires instead; and they also proposed, with the assent of the Council, to apply for a License or Provisional Order. According to a statement in a local journal nineteen-twentieths of the private householders affected had already consented to the erection of overhead wires. It was agreed to refer the question to a sub-committee, but at a later stage of the meeting a telegram arrived from the Board of Trade, in reply to the communication of the Town Clerk, which read as follows:—

> "Question at issue of general regulations, under Section
> "4 of Electric Lighting Act, is still under consideration.
> "Board cannot offer suggestions likely to be of use to
> "Corporation. Think, however, statutory powers should
> "be obtained by License or Provisional Order."

The reading of this telegram seemed to afford considerable amusement to the worthy Councillors, but, on the whole, where local opinion is so nearly unanimous it seems a pity that the undertakers should be saddled with the cost and compelled to submit to the delay of working under the terms of the Act. And in any case we fail to see what responsibility would be incurred by the Town Council if they granted the required permission under the terms of an indemnity agreement with Messrs. Paris and Scott such as these gentlemen would probably be willing to accept.

At the last meeting of the Kensington Vestry, Mr. Lindsay proposed a series of resolutions containing various instructions to the Committee of the Vestry who are charged with electric lighting business. Both these resolutions and the speech in which Mr. Lindsay moved their adoption are of a suggestive character, as will be seen by reference to a later page. Many of the points raised have already been discussed in these

Digitized by Google

columns, but there is one remark to which we particularly wish to draw attention. Referring to a proposal that only those companies should be treated with who would consent to a provision for the sale of their works at the end of 21 years. Mr. LINDSAY, from the point of view of the local authority, strongly deprecated such an arrangement. "If companies were willing," he said, "to give up their rights in 21 years, it led to the inference that they were not financially strong, and wished to obtain a concession which would make them stronger, and the Vestry should be especially careful not to give such companies a monopoly." We have already entered a strong protest against any pre-arranged concession of this character, speaking of it as "a gratuitously suicidal act," and we venture to think that this incident proves that our language was not unduly strong. A transfer of the undertaking on fair terms may, of course, be arranged at any time without departing from the spirit of the Act, but what we do most strongly deprecate is that any one Supply Company should endeavour to outbid another by voluntarily consenting to bind themselves to sell at any earlier date than that provided for in the Act.

THE Geyer-Bristol meter, which is described on a later page, presents several features of interest. Everyone will be struck with the ingenuity and simplicity of the idea, and we are inclined to think that it will prove of some considerable practical value, though it is to be expected that the indications will be somewhat sluggish. As an ammeter, at any rate, its advantages are obvious. It is also satisfactory to know that, according to the recent investigations of C. CRANZ, the differences in the heating power of continuous and alternating currents (of the same mean value) are too small to affect the reading of industrial instruments, although, as a matter of fact, the alternating current has a slightly greater effect. This is a result which we venture to think might have been foreseen, since the heat generated when the current wave is at a maximum must take time to reach the surface of the wire, and we imagine therefore that the higher the thermal conductivity of the metal the more nearly identical will be the effects.

REVERTING for a moment to the opinion recently expressed by our contemporary the *Electrical Review*, that it has been finally recognised in this country that the accumulator affords the only feasible method of utilising electric traction, we note that in its last issue our contemporary devotes two columns of editorials to the discussion and dissection of our demurrer. Unfortunately for the value of this controversial effort, the view which we hold, and which we still think to have been set forth with sufficient plainness, is entirely misstated. So far from saying or thinking that battery traction would *only* be possible when an ideal cell has appeared, what we said was that "an ideal cell would furnish an ideal solution," which is a very different thing. In this workaday world we are usually content (more or less) with solutions of all kinds of problems which are very far from "ideal," and it remains for us to strive to approximate as nearly as may be to the standard of unattainable perfection. In the case in point we proceeded to indicate an important step in this direction which, as it seems to us, might easily be taken. Our contemporary having misread the earlier sentence thinks that this suggestion is a mark of "inconsistency!" As to what else our contemporary alleges against us, for our own part we appreciate too well the distinction betwixt "retort courteous" and "countercheck quarrelsome" to be tempted to pursue the discussion further.

A FRENCH electrician has addressed a letter to the Paris Municipal Council containing a highly novel and original suggestion for the lighting of the streets of Paris by electricity, and, at the same time, for effecting a complete reconciliation between all the conflicting interests involved. It seems that this ingenious gentleman has designed a gas engine measuring only 25 centimetres in diameter, and which can therefore easily be placed within a hollow pillar of the size of an ordinary gas lamp. In the same pillar, above or below the engine, he would put a dynamo, and surmount the whole by an arc lamp, and—*voilà tout!*

UNTIL we have taken an opportunity to inspect Mr. RADCLIFFE WARD'S "electric omnibus" we do not care to express a definite opinion upon its merits. It *may* be a feasible idea so long as it is only proposed to run on asphalte roads without serious gradients. But what will the authorities say? Will not the red flag clause come in? Anyhow, we think it is a great deal too bad of the daily papers to insert such solemn foolery on the subject as has been going the rounds this week. After recounting in great detail the route taken in a trial run, the newspapers assure us that "This is the only electrical omnibus in the world *capable of steering to right and left.*" They omit, however, to state that it is also capable of standing still, of turning round, and even of running backwards! Truly this is a marvellous age!

Bedford.—The Bedford authorities have under consideration the lighting of a portion of the borough by electricity. It is proposed to make use of the existing water power.

Telegraphists' School of Science.—The December number of *Science and Art* (the science teachers' organ) contains a biography of Mr. Slingo, the principal of this school.

The Woolwich Ferry Boats.—The new Woolwich ferry boats, "Gordon" and "Duncan," now under construction, are to be fitted with the electric light by Messrs. Laing, Wharton and Down.

Cowpen.—A special meeting of the Cowpen Local Board was held on Thursday, the 21st ult., at which the tender of Messrs. Nicholson and Jennings for lighting the district by electricity was rejected by four votes to two.

Southwark.—At a meeting of the St. Olave's (Southwark) Board of Works on the 27th ult., it was resolved, on the recommendation of the Works Committee, to oppose the proposed license of the London Electric Supply Corporation to erect and maintain electric lines and works, and to supply electricity within the district.

Submarine Telephony.—Buenos Ayres and Montevideo will shortly be connected by a submarine telephone line 50 kilometres in length. The laying of this cable has been undertaken by M. Ocampo, of Buenos Ayres, MM. Mourlon, of Brussels, being the contractors. The Van Rysselberghe system of simultaneous telegraphy and telephony will be used.

Digitized by Google

Holborn Board of Works.—At a meeting of the Holborn Board of Works, held on Monday last, a letter was read from the House-to-House Electric Supply Company, asking for the consent of the Board for licenses to produce and distribute electricity in the area of the Board's district. The matter was referred to the Works Committee for consideration and report.

Syra.—A correspondent, writing from Syra, says:—"I do not know whether it will interest you to know that for many years past there has existed here the outer walls of a gasworks, and several attempts have been made by various contractors to come to terms with the municipality for the supply of gas, but hitherto all have proved abortive. The municipality is now very anxious to arrange with some electric light contractors."

The Paris-Brussels Telephone Line.—The Paris-Brussels telephone line, the prime cost of which was covered by the first year's receipts, now yields some £4,800 per annum. It will be remembered that the Van Rysselberghe system is used on this line, and since the line is of phosphor and silicium bronze it gives satisfaction. It is also claimed that much of the success attained is due to the Dejongh telephones which are employed.

Commission of Sewers.—At the last meeting of the Commissioners of Sewers the Clerk submitted a notice from the House-to-House Electric Supply Company of their intention to apply for a license to produce and distribute electricity within the City of London. The subject was referred to the Streets Committee, together with a notice of application for Provisional Order by the London Electric Supply Corporation, to supply electricity within the City of London.

The Phonograph in Telegraphy.—A writer in the *Electrical World* suggests that the phonograph seems to be a promising auxiliary to the Wheatstone automatic system. The phonograph can be substituted for the ink recorder, and the signals read off by a Morse operator at his leisure at lower speed. The phonograph motor would require two different speeds—a high speed for receiving the automatic telegraph signals, and a slow speed for reproducing to the Morse operator.

The Passage of the Suez Canal by Night.—No less than 174 steamers, says the *Bulletin de l'Electricité*, passed through the Suez Canal during the month of September at night-time by aid of the electric light. Of these, 33 had their own apparatus; 63 used plant hired from the firm of Gosse, Worms and Co., of Paris; 52 used English plant hired from MM. Bazin; 17 used English plant hired from the Port Said and Suez Coal Company; the remaining 9 using plant hired from Messrs. Wills and Co.

The Lighting of the City.—On Thursday, the 29th ult., at the meeting of the Court of Common Council, the Chairman of the Commission of Sewers (Mr. W. H. Parnell) stated that everything was now virtually in hand for inviting tenders for the lighting of the city by electricity. The committee had decided the lines on which the contractors would be asked to send in their estimates. Although he could not give the exact dates when they would be invited, he could state that all responsible companies would have an opportunity of tendering.

Accidents with the Electric Light.—Two accidents which occurred quite lately show the necessity for well insulated conductors and the use of some uninflammable material wherever regulating rheostats are employed. In a Belgian theatre a rheostat, which had been carelessly screwed on to some woodwork, managed to set it alight. In another case a *danseuse* happened to lean against a pair of electric light leads; the tinsel on her clothes caused a short circuit, and the current set fire to the dress. The flames were fortunately immediately extinguished and no bodily injury resulted.

A Proposed Submarine Cable between Nicaragua and the West Indies.—According to a Panama journal, a contract has been signed between the Minister of Public Works at Nicaragua and Señor Creus, by which the latter gentleman receives permission to land a cable on the Atlantic coast of Nicaragua. The journal states that the cable will connect the Nicaraguan Republic with the West Indies and New York, and that the Government guarantee that the traffic over the line shall not yield less than $6,000 per annum. Work on the cable has to be commenced within the next three years.

The United Telephone Company.—The new multiple switchboard, which has been in course of erection for some time past at the Westminster Exchange of the United Telephone Company, is now at work. The subscribers' wires were transferred from the old board during the night of the 24th ult., without in any way interfering with the continuous service. The current for ringing the subscribers' bells is obtained from a small generator driven by an engine in the basement of the Westminster Palace Hotel. The board contains the latest improvements, and it is anticipated that the service will be much facilitated by its use.

The Society of Telegraph-Engineers and Electricians.—The annual meeting of this Society will be held next Thursday evening, at eight o'clock, when the election of officers and members of Council for the ensuing year will take place. Sir William Thomson is the new president. The following new names of members are submitted for selection for the Council (three to be elected):—W. Lant Carpenter, Conrad W. Cooke, Sir James N. Douglass, J. E. H. Gordon, and Prof. S. P. Thompson. As Associate Members of Council (three to be elected):—S. L. Branton, Augustus Eden, Sydney Evershed, Guy Carey Fricker, A. C. Curtis Heyward, Captain A. E. Wrottesley, R.E., and Arthur Wright.

The Paris Exhibition.—An Order in Council has been issued applying the provisions of the Patents, Designs, and Trade Marks Act to exhibits at the Paris Exhibition next year. Another Order extends the Act to the East Indian colonies of the Netherlands.—At the meeting of the Executive Council of the British Section of the Paris Exhibition of 1889, held on Friday, the 30th ult., at the Mansion House, Mr. H. Trueman Wood, one of the secretaries of the council, was appointed Commissaire Délégué. Sir Polydore de Keyser, late Lord Mayor, will act as Executive President in Paris as well as in London, the present Lord Mayor, Mr. Alderman Whitehead, being the Honorary President.

Messrs. Gent and Co's Illustrated List of Electro-Medical Apparatus.—Encouraged by the sale of their pamphlet on electric bells and kindred apparatus, Messrs. Gent and Co. have lately issued an illustrated and descriptive list of electro-medical instruments made by them. Judging from the large variety of cautery handles, electrolysis needles, surgical lamps, induction coils, rheostats, switches, &c., which are described, we think the catalogue cannot fail to prove of considerable use in the hands of medical electricians, and the frequent occurrence of such archaic terms as Faradism, Franklinism, faradisation, rheotrope, &c., will probably not lessen its value in this direction. Amongst the exhaustive list of batteries we notice the "Gassner" dry cell, which Messrs. Gent and Co. describe with some reason as the "Perfect Medical Cell."

Electric Sugar.—A telegram from New York reports "the first thorough test, with completed plant, of the electric sugar-refining process." The trial took place at the Electric Sugar Company's works in Hamilton-avenue, Brooklyn. The *modus operandi* was precisely similar to that pursued in the tests with "partial plant," viz., raw sugar at the top of the building became "perfectly snow-white crystallised sugar of the highest quality" when it arrived at the bottom 128 minutes after the commencement of the process. The telegram says, "Old refiners present conceded that the granulation was entirely different from that of common refined sugar. Mr. H. C. Highet, formerly of Liverpool, and now of New York, and Mr. Willett, the leading sugar refiner of New York, expressed great satisfaction at the result." The company announce their intention of starting work early next year, when their patent rights will have been secured.

Messrs. Charlesworth and Co.—We are pleased to note that Messrs. S. Charlesworth and Co., electrical engineers, Richmond Hill Ironworks, Oldham, have been awarded a silver medal for the excellence of their exhibit at the Barcelona Exhibition. We understand this firm have now in hand installations for Messrs. Platt Brothers and Co. (Limited), Hartford Old Works; S. R. Platt, Esq., Werneth (both being complete with steam engines, while the last includes a boiler made by the Oldham Boiler Works Company); repeat orders for over 100 lights

Digitized by Google

from the Palm Mill Company (Limited), and also two sets of their portable plant for the night navigation of the Suez Canal for the same firm, for whom the first was made, and which, as we recently noted, passed immediately the company's conditions and trial run. The same firm has also recently completed an installation of over 400 lights for Messrs. J. S. Sykes Brothers, card makers, of Hindley, near Huddersfield.

Valencia Central Lighting Station.—We have frequently drawn attention to the great interest taken in electrical enterprises whether for lighting purposes or for motive power in the town of Valencia. We now have news of the inauguration of an electric light installation there, promoted by the Marquis de Campo. Local electricians believe that it is one of the largest in the world, and the importance of the undertaking may be gathered from the fact that it is said to be capable of illuminating 20,000 lamps, 16 candle-power, a number sufficient to supply the public service, the theatres, and private customers. We understand that the installation has been carried out by Senores Planas y Flaquer of Gerona at a cost of £80,000. We some time ago gave particulars of a large undertaking by which it was proposed to make use of the current of the River Turia for supplying Valencia with motive power and with the electric light. Whether the installation referred to above is a separate undertaking, or is connected in any way with the Turia proposals, is not stated.

Barnet.—At a meeting of the Barnet Local Board, last Tuesday week, a report was presented by the surveyor, giving a list of the electric lamps found out from the 7th to the 16th ult.—numbering in all 13. The chairman (Mr. C. Stevens) reported that the Lighting Committee were going round the district in order to see the effect of the lighting at different points where gas-lamps had been removed and no substitutes provided. The committee had not yet completed their perambulations, and therefore their report was not yet complete. Subsequently a letter was read which had been received from the electric light contractors stating their willingness to supply and fit any additional lamps on the present contract of 16 candle-power at £2. 14s. per annum. They also offered to fit up one 2,000 candle-power arc lamp for the inspection of the Board, without any charge for the experiment. The Clerk said he had seen Mr. Joel since the receipt of the letter, and he was willing to put up a 300 candle-power incandescent lamp free of charge, so that the Board might see the effect of larger lamps, both arc and incandescent.

Coast Defences.—At the Plymouth Chamber of Commerce on the 26th ult., Mr. R. Bayly submitted a motion on the subject of electric coast communication, which he argued should be greatly extended round these islands. Lloyd's had acquired a few signalling stations recently, and he believed the Government had put some twenty coastguard stations in electric connection with each other. But in many respects we were still far behind other countries, notably those whose coasts bordered the Baltic, where telegraph signalling stations were very numerous, and could be used by mariners for ascertaining the state of the weather in the direction they were sailing. Our deficiencies in this respect were conspicuous in such localities as Penarth Roads, Lundy Island, Land's End and the Channel, where vessels are often detained because the Post Office inland system is not connected with the coastguard signalling stations. After some discussion it was decided to send Mr. Bayly and Mr. Bellamy to tender evidence to the Committee on National Defence now sitting in London, and presided over by Lord Hartington.

The People's Palace Technical Schools.—The first distribution of prizes and certificates in connection with the People's Palace Technical Schools took place on Tuesday evening last. Long before the proceedings commenced the Queen's Hall was completely filled by a large and attentive audience. The prizes were given away by the Head Master of Harrow, the Rev. J. E. C. Welldon, who made a short speech, which greatly amused his auditors. After the distribution of prizes, Mr. H. H. S. Cunynghame, Charity Commissioner, spoke at some length on the absolute necessity for technical education in these days of keen competition, and concluded by proposing a vote of thanks to the Rev. J. E. C. Welldon, which was enthusiastically passed. Subsequently a concert was given in the Queen's Hall by the People's Palace Choral Society and the People's Palace orchestra, and a gymnastic display took place in the gymnasium. Excellent results have attended the course of tuition in the Day Technical Schools, the lads undergoing the Science and Art Department examinations in May last with considerable success. The evening classes have proved equally successful; since the present session opened on October 8th, 2,230 students have joined, the average attendance each evening being about 500.

Telegraph Extension in New Zealand.—The *Auckland Press* says that the amount expended by the New Zealand Government on account of telegraph and telephone extensions during last year was £22,984, and the amount proposed to be asked for this year is £20,000, leaving £8,370 for future appropriation. Of the expenditure last year £13,029 was on account of telephone exchanges throughout the colony generally, and was principally for material imported for the purpose. The total capital cost of these exchanges amounted, on March 31st, 1888, to £53,288. The work of the year consisted principally of bringing a large number of small villages into connection with the telegraph system by means of telephones. During last year also a telephone exchange was established at Blenheim. The only important telegraph extension work done during the last year was the erection of the fifth wire on the main north line between Woodville, Tahoraite, and Waipukurae, this being necessary for the proper despatch of the large business on the North Island wires. The further extensions provided for in the estimates of the present year include the erection of a telephone exchange at Greymouth, and also the completion of the Kaipara Heads line, the Middlemarch line, and the line from Waipa to Paru Bay.

Effects of Lightning.—A recent thunderstorm on the West Coast of New Zealand did considerable damage to the telegraph line between Ross and Hokitika. Portions of the wire were melted, and (the lineman reports) "the main body of lightning would then appear to have entered the ground, scooping out a place some 4ft. in diameter, and scattering mud, sticks, and stones, some of which were 10 to 12in. in diameter, in all directions. This, however, does not appear to have exhausted the enormous force, for on the opposite side of the road one would almost think that a ball from a 100-ton gun had been discharged, from the manner in which the scrub, roots, and mud had been sent about, some of it 30 to 50ft. along the road. While this had been going on here as much of the electric discharge as the telegraph wire was capable of conducting had travelled along the wire both ways for about half a mile south and nearly a mile northward, portions making to the earth at nearly every pole in that distance. Some of the poles, of course, have been shattered to pieces and scattered along the road or in the bush, while others have had pieces of various dimensions cut out or split off in the effort of the mysterious force to find the shortest path to the earth. For several chains the telegraph wire has the appearance of being bent at short distances as if it had been wound on a cylinder, having sharp projections at regular intervals."

Bradford Corporation Central Station.—Considerable progress has been made during the last few weeks with the work of erecting the central electric lighting station which has been undertaken by the Corporation of Bradford. Workmen have also been employed for some days in laying the cables along Kirkgate and some of the other thoroughfares in the centre of the town, and it is now believed that the whole of the preparations will be completed before Christmas. A sum of £15,000 has been granted by the Town Council to the Gas Supply Committee to cover the cost of the installation and incidental expenses connected with it. Should, however, the experiment be successful, and the tradesmen and others in the centre of the town show a disposition to avail themselves of the facilities offered them by the Corporation for lighting their premises by electricity, it is probable that the area of supply will be extended. The number of applications which the committee have already received lead them to expect that such an extension will soon become necessary, and, foreseeing this contingency, they are carrying out the present works as though they were

Digitized by Google

but a part of a larger scheme, which the Provisional Order obtained for the purpose authorises them to effect. Two main cables are being laid under the roadways from the depôt along Market-street to the Town Hall, and up Darley-street as far as the Free Library, and both these public buildings will be lighted by electricity.

Royal Institution.—At the meeting of the Royal Institution on Monday last, the special thanks of the members were returned for the following donations to the fund for the promotion of experimental research:—Mrs. R. J. Mann (for the late Dr. Mann), £20; Mrs. Bloomfield Moore, £50; Warren de la Rue, Esq., £100. The following are the lecture arrangements before Easter:—Prof. Dewar, six lectures (adapted to a juvenile auditory) on Clouds and Cloudland; Prof. G. J. Romanes, twelve lectures constituting the second part of a course on Before and After Darwin (The Evidences of Organic Evolution and the Theory of Natural Selection); Prof. J. W. Judd, four lectures on The Metamorphoses of Minerals; Dr. Sidney Martin, four lectures on the Poisonous Action of Albuminoid Bodies, including those formed in Digestion; Prof. J. H. Middleton, four lectures on Houses and their Decoration from the Classical to the Mediæval Period; Prof. Ernst Pauer, four lectures on The Characters of the Great Composers and the Characteristics of their Works (with illustrations on the pianoforte); and eight lectures by the Right Hon. Lord Rayleigh on Experimental Optics (Polarisation: the Wave Theory). The Friday evening meetings will begin on January 25th, when a discourse will be given by Prof. G. H. Darwin; succeeding discourses will probably be given by Prof. W. C. M'Intosh, Sir William Thomson, Prof. A. W. Rücker, Mr. Harold Crichton Browne, Prof. Oliver Lodge, Prof. Archibald Geikie, the Rev. Alfred Ainger, the Right Hon. Lord Rayleigh, and other gentlemen.

The Telegraph System of the Argentine Republic.—It would be strange indeed if electric enterprises in the River Plate were not stimulated by the "boom" that has lately been developing in that country. Money has this year been flowing into the country in millions of pounds sterling, the proceeds of loans raised in Europe by the Federal and Provincial Governments. Much of the activity is unfortunately of a speculative character, and may better be described as an inflation; but that there is a considerable increase in the *bonâ fide* trade movement of the country cannot be doubted. A Buenos Ayres paper, referring to the activity of the Postmaster-General, remarks that new offices are being opened daily to facilitate rapid postal and telegraphic communication, and that official is described as indefatigable in having the telegraph lines repaired and, where necessary, reconstructed. In a report to the Minister of Public Works, he states that he has had various sections repaired and reconstructed, amounting in the aggregate to 6,449 kilometres, at a cost of $150,000. He reports that communication in the north of the country, where the network is more complete than elsewhere, has been entirely reorganised and is now quite regular, all interruptions and delays having been done away with. There are at present 4,026 kilometres in course of construction, representing a total outlay of $674,715, and no less than 2,849 kilometres remain to be laid, for which an outlay of $454,630 is required. Congress will be asked to grant the extra expenditure required by the department. It is urged in the interests of the commercial community that every corner of the Republic should be placed in communication with Buenos Ayres; and with Continental financial syndicates ready to lend freely to Argentine borrowers upon almost any pretext, there is little doubt but that this desideratum will be attained. Whether the pace at which Argentines are rushing to pile up debt can be long maintained is another question into which it is not here our province to enquire.

Chelsea Vestry.—At the last meeting the Electric Lighting Committee reported that they had considered a letter from Major Waller, on behalf of the London Electric Supply Corporation, requesting permission to lay an underground cable along Pavilion-road, as shown on an accompanying plan, and the committee recommended that the application be granted subject to the terms of the Chelsea Electric Lighting Order, 1886, being embodied in an agreement between the coporation and the vestry, and during the pleasure of the vestry. With reference to this recommendation, a deputation of four gentlemen representing the Chelsea Electric Supply Company was introduced by General Webber.—General Webber proceeded to ask that the vestry would not approve the recommendation of the Electric Lighting Committee set out above. He did so on the ground that such an introduction by the vestry of competition in the supply of electric light in that part of Chelsea known as District A, for which his company had a provisional order, would be a serious disadvantage to them. The deputation having retired, Mr. Mossop then moved the adoption of the committee's recommendation to grant the application of the London Electric Supply Corporation for permission to lay an underground cable along Pavilion-road during the pleasure of the vestry. He reminded the Board that the Electric Lighting Act was opposed to the establishment of any monopoly. The vestry had also to protect itself from the introduction of overhead wires. They had no power to insist on underground wires, but both the Cadogan Electric Light Company and this London Electric Light Corporation relieved them of the difficulty by volunteering to give undertakings to lay their wires beneath the pavement. The vestry having thus got the power into its hands again should not sanction any monopoly, but only consider the interests of the ratepayers.—The Chairman then put Mr. Mossop's motion to the vote, and it was carried unanimously, the deputation being informed of the decision.—It was also resolved, on recommendation of the committee, that the application of the Cadogan Electric Light Company for permission to lay a 2in. iron pipe beneath the pavement from their works in Manor-street to the Chelsea Embankment be granted, and also that in all future cases in which the pavement is disturbed for the laying of electric wires or cables the vestry relay the pavement at the cost of the company.

Lecture on Electro-Physiology.—On the 6th ult., at Owens College, Manchester, Professor Stirling delivered a lecture on the electrical properties of the tissues, but especially of those composing the nervous system. There are about fifty species of fishes which are known to have specially modified organs for the generation and discharge of electricity. These organs when at rest do not discharge their electricity; but if the animal be irritated electrical shocks are discharged, which in some fishes are very powerful indeed. By means of electrical discharges these animals not only stun their prey, but they ward off the attacks of their enemies. The animal may discharge its batteries voluntarily, but after having done so for a considerable number of times the electrical organs become fatigued, just as muscles after severe exercise are fatigued. At first sight it might seem remarkable that certain animals are provided with structures which evolve powerful discharges of electricity. This, however, is not by any means the most remarkable fact. When we know that the whole of the body of the animal is traversed by the electrical current at the moment it is discharged, it does seem far more wonderful that the tissues of the animal itself are not thereby affected; not even a muscle is caused to contract, although the discharge must necessarily traverse the nervous system as well as the muscles. The animals, therefore, have an immunity from the effects of their own shocks. Darwin admitted that the presence of these organs in a limited number of fishes was a fact not easily explained on the evolution hypothesis. Recent researches, however, have shown that the electrical organs are really modified muscular organs, or the terminations of nervous structures in muscles. This fact greatly simplifies the problem. Muscles and nerve, however, evolve electricity in the living condition; and a variation of the electrical conditions of a muscle, a nerve, or even of protoplasm generally is one of the best signs of the vital activity of these structures. With Galvani's experiments on the twitchings of the limbs of frogs, there commenced the investigation of electrical phenomena, which have led to such splendid results, not only in physiology, but to the development of new means of producing electricity and its numerous applications in the arts. The lecturer demonstrated the classical experiments of Galvani, Volta, Noboli, Du Bois Reymond, and others, showing historically on what lines our present knowledge of animal electricity had been reached.

LIGHTNING CONDUCTORS.—IV.

BY DR. OLIVER LODGE.

(Continued from page 71.)

Application of Theory to the Last Recorded Experiments.

26. The L loop of the circuit in these last observations consisted of the No. 19 copper wire round the room, and some ordinary connecting wires in addition, the self-induction of which portions may be estimated as about 100 metres. It is fortunately unnecessary to know it exactly, because it is almost lost in the much greater inductance of the No. 19 lead.

Collecting the data required from Article II., and reproducing them here, we have, for the inductance, length, and ordinary resistance of the conductors employed, the following values:—

	Self-Induction L	Length l	Resistance r
	Centimetres.	Centimetres.	Ohms.
No. 19 copper + connections ...	67,000	3,500	3
No. 1 copper	39,000	2,700	·0254
No. 1 iron.....	39,000	2,700	·0881
No. 18 iron	55,000	3,000	3·55
No. 27 iron	63,000	3,000	33·3

The first thing necessary to be calculated is the frequency of vibration; and inasmuch as it is improbable that in any of these cases is the resistance sufficient to make the coefficient m of § 2 comparable in size to n, unless the resistance of the A spark be supposed excessive, I shall proceed to calculate n in the first instance as simply equal to

$$\frac{1}{\sqrt{\{S(L+L_0)\}}}.$$

The electrostatic capacity charged is, the jars, which together equal 28 metres, and the No. 19 lead and connections, which equal four metres more. So the value of S is 3,200 electrostatic units.

When either of the No. 1 leads is the alternative path the total self-induction of the whole circuit is

$$L+L_0 = 67000 + 39000 = 106000 \text{ electro-magnetic units.}$$

Before multiplying these quantities together we must reduce them both to the same units, or, what is better, express both fully and without any convention, as $S = 3200\ K$ centimetres, and $L+L_0 = 106{,}000\ \mu$ centimetres.

So the product

$$\sqrt{\{S(L+L_0)\}} = 18400\ \sqrt{(\mu K)} = \frac{18400 \text{ centimetres}}{3\times10^{10} \text{ centimetres per sec.}}.$$

Hence $$n = 1{\cdot}63 \times 10^6 \text{ per second,}$$

and the frequency, being $\frac{n}{2\pi}$, is in this case just about one quarter of a million complete alternations per second.

A similar calculation for the other leads enables us to fill up the column headed n in the subjoined table.

27. The next thing is to reckon the effective resistance to currents alternating at this rate. The rapidity being so great one may use the simple formula of § 2, which makes the effective resistance the geometric mean between r and $\sqrt{(\frac{1}{2}n\mu l)}$; and hence the next column of the table is calculated, and the column of resistances headed R_0 filled up from it. Unfortunately there is great uncertainty as to the proper value of μ, the magnetic permeability which should be used. Prof. Ewing has found values of μ varying from 60 to 130 or so for hard iron or steel; and all kinds of values for very soft iron up to 2,000, and even, when vibrated, up to 20,000. Now the skin of wires is liable to be hard, and, as they tend to get magnetised by the current in concentric rings, the lower values of μ seem most probable, at least for thin wires. None of the wires were softened or annealed in any way—they were put up as bought at an ironmonger's. It will be well to try a few experiments with some specially selected iron wire. Meanwhile, as I am uncertain what value of μ to employ, I propose to try two very different ones, and see what happens in each case. First I will consider $\mu = 100$, and then $\mu = 2500$.

The quantity $\sqrt{(\frac{1}{2}n\mu l)}$ has the dimension of a resistance, and to bring it to ohms it is divided by 10^9. The value of $n\,L$ can be similarly expressed.

28. The rest is pretty simple. Having filled up the R_0 column as the mean of the preceding and of r, we calculate impedance by reckoning the value of

$$\sqrt{\{R_0^2 + (n\,L_0)^2\}}.$$

For the No. 1 copper wire this comes out 64 ohms.

One estimates the potential V_0, to which the jars were charged, by the length of the A spark, and thus calculates the current amplitude

$$C_1 = \pm\frac{V_0}{n\,(L+L_0)}.$$

The A spark being 2·4 centimetres long, between the knobs of the universal discharger, will be found, by means of the information contained in § 21, to correspond with a length of spark 1·5 centimetres between flat plates. This gives as the initial potential, V_0, 50,000 volts; and accordingly the maximum current comes out 284 amperes for the circuit including the No. 1 copper.

Between positive and negative values of this magnitude, the current oscillates 260,000 times a second until damped out by the exponential term and dissipated into heat. This process does not take long. A column shows the time taken for the current amplitude to decay to one-millionth of its initial value, *i.e.*, 14 times what is ordinarily called the "time constant." The next three columns show the proportion of current amplitude remaining after 1 complete vibration, after 10 vibrations, and after $\frac{1}{4}$ of a vibration.

Near the middle of the table is a column showing the estimated potential available for the B spark, allowing nothing for damping. This is got by simply multiplying the impedance of the alternative path and the current amplitude. Dividing this by 33,000, we get the calculated length of B spark between flat plates; and to obtain from this the corresponding length of spark between the actual micrometer knobs we have to make use of information contained in § 21. These lengths are tabulated in the adjoining column, and to compare with them the experimentally observed numbers are tabulated alongside of those with which they best agree. Considering that the calculation attempts *absolute*, and not merely relative values, the agreement is surprisingly close, for the numbers calculated by means of $\mu = 100$.

29. But then, so far, no allowance for damping has been made. We must next make the supposition that the B spark lags a quarter period behind the A spark, so that the current amplitude has had time to be slightly reduced. The theoretical B spark thus obtained is entered in the last calculated column of the table, and alongside of it the experimental numbers are again quoted, but this time they agree best with the larger value of μ.

As a matter of fact, this lag of a quarter period *must* occur, in order to give time for the current to rise from nothing to its maximum value. The only question is whether the B spark does not lag a little longer, and only occur at the second or third oscillation. If so, of course damping becomes more important; but I see no reason making it probable that if it cannot jump at first it will be able to jump at all. I propose, however, to settle this point by arranging the two sparks A and B alongside of one another, and examining them both in a very rapidly rotating mirror.

30. There is just the possibility that the B spark jumps the gap before the current has had time to be fully excited in the alternative path, and if so, the circumstances regulating its critical value must be different; the hypothesis really requires a fresh theory, in which the electrostatic capacity of the alternative path lead will play an important part. While testing the theory originally suggested in Article I., we must ignore this possibility. Besides, it can be tested experimentally by cutting the wire forming the alternative path at its middle, and seeing whether the length of the B spark is or is not affected. This I have done, the numbers will be given later on;

* Or time required for the charge to be permanently reduced to one-millionth of its original value.

suffice it to say now that the B spark is immensely lengthened by the change, showing that the wire acts by conduction, not by electrostatic displacement.

31. The column of the table headed "Damping coefficient" gives values of m calculated on the assumption that the resistance of the spark itself is negligible. This may be untrue, but I do not know how to estimate it. If it is more than five or six ohms it ought to be taken into account; though its only effect will be to slightly increase the damping coefficient. Towards the end of the discharge the resistance of the spark may become very large, but by that time the B spark is over.

The last entry in this damping coefficient column, 1·65 million per second, is the value of m for the No. 27 iron wire on the improbable assumption that $\mu = 2500$. This value of m is actually bigger than n, which is only 1·47 million per second, so the whole second approximation breaks down for this case, for it depends on m^2 being moderately small compared with n^2. The column headed n ought indeed, strictly speaking, to be headed $\sqrt{(n^2+m^2)}$; and, knowing this, a more correct value of n can easily be calculated by successive approximations, except for the last line of the table. It is because of this failure to satisfy the second approximation conditions that no further entries are made in the last line of the table. To work out the results of this case the third approximation of § 5 is necessary. The most generally interesting part of the table is included between a pair of double lines.

(To be continued.)

THE WESTINGHOUSE ELECTRIC COMPANY.

The handsome folio volume of some eighty pages, artistically bound, illustrated with excellent wood engravings, and embellished with many decorative designs, which lies before us, purports to be a "circular" from the Westinghouse Electric Company, of Pittsburg. Amongst circulars this publication is probably unique, not so much, however, from its elaborate and artistic get-up as from the fact that it contains an exposition of the results attained by the Westinghouse Company which, whether from their magnitude, their novelty, or their success, must be reckoned among the most marvellous achievements of the present age. In the first *eighteen months* of its existence over one hundred central lighting stations were equipped by the Westinghouse Company, and at the present time—less than two years from its foundation—the company has manufactured and sold the complete outfit for *one hundred and twenty-five* central stations, supplying over 210,000 lamps. Such a record as this could only have resulted from the most favourable combination of what may be called the internal and external conditions. Technical and commercial ability of the highest order, combined with ample capital, unfettered management, and a practically perfect organisation were needed, whilst, above all, the presence was indispensable of that peculiarly Yankee quality of go-aheadness which, to the more sober British mind appears always to verge on the reckless and which yet generally contrives to fall on the right side of the fence. All this would not, however, have sufficed to account for the unprecedented success of the system, but for the fact that in America the field was already white unto the harvest. Low-tension distribution had practically arrived almost at the end of its tether, and the country, already familiar with the advantages of electricity, was prepared to welcome with open arms a system of which the advantages were so transparent. The cheap and rapid manner in which the conductors could be placed was doubtless sufficient by itself in many cases to ensure its adoption.

The American mind does not wait "till somebody else has tried it first," and the fact that a system is in the earliest stage of practice seems generally to be an additional recommendation. The result is that already, and for some time past, the company keeps a wholesale stock of complete central station outfits, so that on receiving an order the entire plant can usually be forwarded within twenty-four hours!

In proceeding to note some of the points in this manifesto which are of chief interest to the English reader, it should be

Digitized by Google

stated at the outset that the "circular" is by no means written with a view to furnishing technical details; on the contrary, these are sometimes avoided with marked care. The object in view is definite and practical, namely, to demonstrate to the world at large the superiority (from the Westinghouse point of view) of the alternate over the continuous current in point of economy, efficiency, simplicity, and flexibility, and, incidentally, no doubt, to show also that their own system in particular combines all these advantages in a special degree. It must, however, be remembered that the comparison is made from the American standpoint, and, therefore, almost solely with the Edison or other low-tension systems, and not with the methods of battery transformation which are now somewhat in vogue with us.

On the opening page, in a general comparison of the alternating with the continuous current systems of distribution, we are told that the former "involves far less complication of parts by retiring altogether a long list of commutating, regulating, and distributing devices, now known to be entirely unnecessary." This is a claim which, though it would be hard to gainsay, has not, we think, been fully realised by the advocates of alternate current distribution in this country. The supposed difficulty of regulation and of running alternators in parallel has again and again been alleged as a serious objection. At the same time the truth of the assertion receives confirmation from the practice at the Grosvenor Gallery, where the method of regulation is reduced to the utmost limit of simplicity.* As to parallel running, neither the Westinghouse nor the London Electric Supply Corporation find it necessary to the working of their systems, though we still venture to believe that this method will, in many cases, prove to be both practicable and advantageous.

The next point to which we may refer is that of lamp voltage, in which there is a marked difference betwixt English and American practice. The Westinghouse Company has adopted 50 volts as the standard for their secondary circuits. Now, although we have several times taken occasion to recommend the adoption of the same figure in this country, yet we have done so for reasons of a different character from those which appear to prevail in America. We read with some surprise that "all manufacturers would be glad to use a lamp of as low resistance as possible for the sake of efficiency," and again, "a high-resistance lamp is inherently a low-efficiency lamp." If the term efficiency is employed in the usual sense, we can only suppose that this points to some inherent peculiarity in lamps of American make—at any rate, we have yet to learn that this consideration applies to the lamps made in England. The strong reason which we discover in favour of the 50-volt lamp is, that it is more easy to manufacture such lamps in large quantities to a uniform standard, and therefore its general use would directly facilitate that substantial reduction in the price of lamps which is so much to be desired. We think also that there can be no doubt that these lamps have a somewhat longer life. Of course the matter is to some extent in the hands of the lamp makers, who might easily reduce the price of lamps of lower voltage; but then again, so long as people will pay for an inferior lamp, they may not think it to their advantage to foster the use of lamps of greater durability. If so, we think their policy a mistaken one. The lamps made by the Westinghouse Company (under the Sawyer-Man patents) are of 10, 16, 20, 25, 32, 50, 75, 100 and 150 candle-power, and all of 50, 75, or 100 volts. The two largest sizes have each two filaments in parallel. The 50 and 75 candle-power lamps are strongly recommended by the company for the lighting of retail shops.

Great stress is laid upon the fact that the difficulty of calculating the proper size of the mains in the low-tension system practically disappears under the high E.M.F. which is used with the alternating current. If the initial difficulty were the only thing to be considered this would be of less importance, but the serious nature of the objection arises from the fact that an extensive addition or alteration to the number of lamps may at any time upset the whole of the arrangements, and necessitate a serious expenditure of time and money.†

* See *Electrician*, November 9, 1888.

† In a Paper on "Central Station Lighting in Germany," which appears elsewhere in this issue, will be found an interesting account of the "model" system of determining the size of mains for low-tension distribution.

Although all Westinghouse dynamos are built for a uniform potential difference of 1,000 volts, yet in practice they do not restrict themselves to this limit for the primary circuits. If any circuit is of specially great length it is fed from a converter placed in the central station, by means of which the potential is raised to any required extent. Thus, one dynamo is sometimes employed to feed two or more circuits at different potentials. The circular justly remarks that this affords a beautiful illustration of the flexibility of the system. It is possible that the capabilities of the Westinghouse high-speed engine have had something to do with determining the limit of output, but at present only four sizes of machines are constructed; these are for 500, 750, 1,500, and 3,000 lights respectively. We may remark that the pulleys of these machines are made of compressed strawboard, which is said to have been found by experience to excel other material for belt traction.

The design of the Westinghouse converter has already been described in our columns,* and need not be repeated. But we may mention that the excellence of the design seems to be proved by the following statement:—"In our laboratory experiments we have repeatedly overloaded converters until the insulation was entirely burned off, leaving the coils bare, and have found that it was, even under these circumstances, impossible to force the primary current on to the secondary circuit. *In short, it is essentially impossible for the primary current to pass the converter and enter the building, nor do we believe that there has ever occurred or ever can occur an instance of this nature.*" The experiment, however, was probably made with only 1,000 volts on the primary. It would be interesting to know whether the same result would be attained with a converter built for, say, 2,500 volts, and in any case we should be rather slow to endorse this view to its full extent. All Westinghouse converters are enclosed in air-tight casings of cast iron, and they have been placed in every conceivable situation within or without the buildings to be lighted. The largest size at present made furnishes a secondary current of 40 amperes. The practice of coupling the secondary circuits of several buildings in parallel and feeding them from one group of converters is not recommended, though it is occasionally resorted to. On special circuits of 2,000 or 3,000 volts two or more converters of the ordinary type are used with the primaries joined in series. Full advantage is taken of the properties of the alternating-current in the matter of regulation by impedance coils with a trifling expenditure of energy. We expect to see this feature largely resorted to in the alternating-current systems which are now being developed in this country. For domestic installations a "house regulator" is provided, which can be set to give any one of seven different voltages on the lamp circuit. This, however, is not a mere impedance coil arrangement, since on a 50-volt circuit the following successive steps may be taken—25, 30, 37½, 45, 50, 52½, and 55 volts. Thus it will be seen that the regulator enables the consumer to burn his lamps *above* the normal voltage whenever extra brilliancy is desired. At present we do not profess to explain the construction of this apparatus, but it is evident that it fulfils a most useful purpose.

Another device, of a somewhat more novel character, is that of the so-called "compensator," which is used in the central station in order to determine the actual difference of potential at any given moment at any point of the line. In the Edison system it will be remembered that this is accomplished by means of "pressure wires," which are run back to the station from the ends of the feeders. In the Westinghouse system the compensator is a species of impedance coil which is placed in series with a voltmeter, *and around the core of which the main current also flows*, the coils being so wound that the current in the main tends to decrease the reading of the voltmeter. Although the construction is not described in detail, it is easy to see that by plugging in more or less turns of the main coil the voltmeter can be made empirically to read the volts at any one of several points on the line. When the instrument has been adjusted for the required conditions, the dynamo-tender has then only to vary the resistance of the exciting circuit to keep the voltmeter needle at a proper reading. A similar device for continuous currents has, we believe, been carried out by the engineers of the Anglo-American Brush Company in England.

* See *Electrician*, August 26, 1887.

The Westinghouse switches and fuse blocks, some of which were shown in this country a year or more ago, cannot be said to have created a very favourable impression. Even the largest switches here illustrated appear to be mounted on wood. This is a practice which certainly will not be followed in this country, even though it be proved that an alternating current has less tendency than a continuous current to form an arc under similar conditions. Speaking of lamp sockets in this connection we read :—"It must be remembered that the alternating current practically kills its own spark by its reversals, and hence the contact pieces in the socket suffer practically nothing from deterioration, and admit of the whole construction being direct and simple."

Our space does not admit of further detail in this issue, but next week we shall return to the subject.

(To be continued.)

THE ROYAL SOCIETY.

The annual meeting of the Royal Society was held at Burlington House on Friday last, when the Copley Medal was presented to Prof. Huxley for his morphological and histological investigations, and the Davy Medal to Mr. W. Crookes for his investigations on the behaviour of substances under the influence of the electrical discharge in a high vacuum.

At the anniversary dinner, held the same evening, in returning thanks for the health of "The Medallists," Mr. Crookes said :—In the absence of Prof. Huxley, who, unfortunately, is unable to be present this evening, I have been asked by our President to return thanks for the Medallists. The professor, in whose shoes I now stand, has lately put it on record that for twenty years he never rose to make a speech without his tongue cleaving to the roof of his mouth through sheer nervousness. I, on whom his duties have fallen, but, alas ! not his mantle, crave your indulgence for that nervousness for which I can quote so excellent an authority, and beg you to bear with me patiently in what must be as great a disappointment to you as it is to myself. Although I feel it embarrassing to take the place of a philosopher so renowned as Huxley, I am bound to say that even he cannot receive the Copley Medal—the ancient olive crown of the Royal Society, as it was called by Sir Humphrey Davy—without regarding it as the culminating honour of his scientific career. I am also bound to say that the award of this medal to such a man as Huxley confers at least as much honour on the Royal Society as on its renowned Professor. As regards the other recipients of the medals, Prof. Tacchini, the Romford Medallist, Baron Ferdinand von Müller and Prof. Osborne Reynolds, the Royal Medallists—coworkers with myself in the very varied departments of science—judging from my own feelings at the present moment, I cannot do better than express on their behalf the sincerest gratification at the high recognition you have bestowed on their scientific work. For my own part, as the Davy Medallist, I may perhaps be permitted to speak at somewhat greater length. Thirteen years ago in this very room, at the anniversary dinner of the Royal Society, I had the honour to return thanks to this Society for conferring on me the distinction of a Royal Medal. The President, Dr. Hooker, in handing to me the medal, referred to the then novel instrument the radiometer, and in the course of his remarks he made the following observation : — "It is the mystery attending this phenomenon that gives it its great importance. There is evidently some action going on with which we are not at present acquainted ; and there is no saying what a thorough investigation into the cause of the phenomenon may lead to." From that date to the present I have not ceased to work at the elucidation of the mysteries accompanying high vacua. During this interval of thirteen years the theory of the radiometer has been established on a firm basis. Since the advent of the radiometer the otheoscope has been devised and its action elucidated ; lines of molecular pressure in high vacua have been illuminated so as to render visible to the bodily eye those actions which hitherto had been seen only by the eye of faith ; molecular shadows have been projected ; luminous streams have been deflected and magnetised ; platinum has been melted by molecular impact ; the existence of matter in a fourth state—"radiant matter"—has been demonstrated ; and the strikingly brilliant phenomena of phosphorescence in high vacua have been discovered. The results of these investigations I have embodied in ten memoirs and Bakerian Lectures, which have appeared in the *Philosophical Transactions*, in eighteen Papers which have been inserted in the *Proceedings* of the Royal Society, and in fifteen other Papers published elsewhere. In the spectroscopic examinations which these researches necessitated, I constantly met with a bright, citron-coloured line, sometimes strong, at others only a ghost of a line, but always in the same place, and presumably due to the same cause. The hunting out of this phantom line has been a work of many years. At last I found it to be due to yttria, while a corresponding red line was tracked to samaria. Here a new field, indeed I may say a new world, of research unfolds itself to the chemist. The phosphorescent light from yttria gave in the spectroscope a complicated and beautiful series of coloured lines. But these lines varied in different specimens of the same earth from different localities, some being strong and others weak almost to extinction. Chemical tests showed that in each case the earth was free from known impurity, and for a long time the interpretation was inexplicable. I was confronted with a series of inscriptions from the molecular world, written in a strange and baffling tongue, and requiring a Rosetta stone to give the first step to decipherment. How the key of the mystery came into my hands, and what resulted therefrom, are now matters of history. The meaning of the lines, their positions and variations, is gradually becoming clearer and clearer, and to me this is what they seem to be saying. They tell me that in matter which responds to every test of an element, which possesses an atomic weight and combines with other matter in definite proportions, there still exist minute shades of difference among which a process of selection is possible. They tell me that the time-honoured distinction between elements and compounds, as it exists in the Lavoisierian and Daltonian chemistry, must be modified to make room for a vast array of intermediate bodies, or as I have elsewhere called them Meta-Elements, capable of isolation and identification. They tell me that there exist degrees of rank in the hierarchy of the chemical elements, some being, so to speak, more elemental than the others, some still waiting to be discovered, whilst others may have disappeared and are no longer existent under the conditions in which we are now placed. They tell me, again, that our chemical elements are products of the action of forces on a state anterior to matter, which I have designated as Protyl ; that these elements owe their present stability in that they are the outcome of a struggle for existence, a Darwinian development by chemical evolution ; that just as in the organic world we have the "survival of the fittest," so here we have the "survival of the most stable" or possibly of the "most inert." There are other lessons as yet only indistinctly whispered, lessons which, possibly to-day but certainly in days to come, will be seized on and interpreted. But I will no longer weary you with speculations which have not yet received full and final confirmation. It only remains for me to thank you for the high distinction of the Davy Medal—a distinction all the more welcome as it has only once previously been awarded to one of our own countrymen. I deeply appreciate the kind reception you have given me and the very gratifying remarks with which the presentation has been accompanied. Refreshed and stimulated by your friendly words of encouragement, I shall continue to apply myself to what Darwin called "the vivid pleasures of investigation." I shall attack with renewed energy the problems of radiant matter spectroscopy, and do my utmost "to pluck out the heart of the mystery."

CENTRAL STATION PRACTICE IN GERMANY.*

BY MR. F. J. PARSONS, PH.D.

Electric lighting on a commercial scale is not as old a thing in Europe as it is in this country [the United States], nor has it to this day attained to the same dimensions that it has here ; so you will not, I trust, be disappointed if I do not report to you any strikingly new developments in anything connected with central station lighting.

Theatres in Germany are mostly the property of either the general or the city Government, and no pains or expense have ever been spared to make them as good, and, above all, as safe as possible ; so it is not a matter of surprise to find the electric light first adopted in the theatres. The first theatre on the Continent to be lighted by electricity was the theatre in Brünn, the capital of Moravia, in the year 1882. Then followed, when this one proved to be such a success, the Royal Theatre at Munich at the time of the Electric Exhibition in that place in 1883.

This was the first station put in by the German Edison Company, and was but the first of a long series of similar enterprises all over the country.

As you see by the dates above mentioned the Germans were behind the Americans in point of time, behind even the English, for that matter, as the Savoy Theatre was lighted by electricity as early as 1881. But you can see the characteristic thoroughness with which the German does everything, from the fact that even in these first theatres that were lighted by electricity, that was the

* An address delivered to the Boston Electric Club.

Digitized by Google

only method that was used, and there was no compromise made with gas, using electricity when everything worked well, and falling back on gas when a bearing got hot, or a fuse blew out, or any other of those untoward accidents happened that are so annoying in a large central station, and so absolutely disastrous in a comparatively small plant like that of a theatre. These theatres, however, are not even piped for gas at all, and to reduce to a minimum any danger of being left in the dark, the entire plant is put in in duplicate—lamps, wires, dynamos, engines, and everything; the only difference between the two being that the reserve plant is not as large as the one in ordinary use, so that if anything should happen to the regular plant in daily use the reserve plant could be immediately called into service, and the only difference would be, even if the first were entirely disabled, that the theatre would not be quite as brilliantly illuminated as before.

The motive power there, as here, depends on circumstances, being sometimes water, sometimes steam, and often gas engines. The Deutzer Gas Motor Company, for instance, furnishes excellent motors for electric light purposes up as high as 150 horse-power each, that do not use more than 15 cubic feet of gas per horse-power-hour, which, at the present price of gas in Berlin, makes an expense of only 1·2 cent. per horse-power-hour for fuel. Another advantage that gas motors have over steam engines in German cities is that a gas motor can be put up anywhere without special permission from the city authorities, and without increasing the insurance rates, while it is sometimes quite difficult to get permission to put up a steam engine.

In the business portion of Berlin it is only on the promise of taking the most extraordinary precaution to deaden the sound and to prevent accidents that one can get the necessary permission from the city authorities. For instance, the entire plant of the first electric light station is in the basement of a building on Friedrichstrasse, one of the busiest streets in Berlin, and, except for the white puffs of the exhaust steam that are seen to come out from the roof at night, no one even in the building could tell that there was a steam engine anywhere near them.

They use smoke-consuming furnaces, so there is no disagreeable smoke. All the foundations of steam engines and dynamos are carefully isolated from the foundations of the building itself, to prevent the inevitable vibration of the high-speed engines from being conducted to the walls of the building. The pulleys are covered with leather to deaden the sound of the running of the belts, and the exhaust steam is carried off so that you do not hear that characteristic sound, so that, even standing on the floor directly over the engines, it is impossible to tell whether they are in motion or not.

The question between one or two large low-speed engines and a larger number of small but high-speed engines has been decided, about as it has been in this country, that in most cases it is more economical to run a large number of small ones.

The method of transmission is about the same there as here, direct coupling being seldom used, but wire or hair ropes running in grooved pulleys are quite common. As to the dynamos used over there, there is perhaps not as large a variety in the market as here.

The two firms who have almost a monopoly in building dynamos for Germany are Siemens and Halske of Berlin, with an almost exclusive control over the market in North Germany, and Schuckert of Nürnberg, holding a similar position in South Germany. Schuckert was one of the first who was successful in making a compound dynamo that was of practical value, and as early as 1883 had built one that did not at any point vary more than one volt on gradually increasing the current from no load to full load. The Schuckert machine is a flat Gramme ring, which on account of the high peripheral velocity that it is possible to give to the armature without unduly increasing the speed, is especially adapted for a high constant potential. Still, by putting in plenty of iron to reduce the magnetic resistance of the ring, it is possible to make an excellent machine for incandescent lighting. By far the majority of dynamos in Germany, however, are built by Siemens and Halske.

The machines they build for stations that they run themselves are of the type best known, perhaps, in this country as the Kapp machine. Like all other machines built by Siemens and Halske, every part of the machine has been worked with the greatest care to make it comply with all the requirements of a dynamo built on scientific principles, and all the mechanical details are carried out with the most thorough workmanship. The armature core is made of iron wire wound in several distinct compartments around a frame insulated from the shaft, so that there is not the heating that one finds in the so-called Siemens armature, where the iron discs are in direct contact with the shaft, thus giving rise to eddy currents and not allowing for ventilation, while in the armature as built by Siemens and Halske there is abundant opportunity for ventilation. The winding is of course the usual Siemens', or, as it should be called, the Von Hefner-Alteneck method. The commutator itself is a very simple affair, consisting of the usual bars of copper, but only fastened at one end, and nothing but an air space between each for insulation. This commutator they have found very successful, and have adopted it on all their machines. Among other things it has this great advantage, if anything happens to one or two segments they can be taken out to be replaced by simply unscrewing one or two screws.

Besides these machines which they build for central stations that they put in themselves, they have a special contract, by the terms of which they have to furnish all the machines of the Edison type used by the German Edison Company. They are made with all the latest improvements both in the general form of the machine and in all its details; as in many other German machines that are intended to run at a high speed, the bearings are kept cool by a circulation of water being kept up around them. These machines, as they are intended for central station use in the strict sense of the word, are all simple shunt machines. Although there are those here, no doubt, who will dispute my statement, there is no question in the minds of electricians over there that it is more than useless to compound a machine that is to be used in any central station of any size, *i.e.*, in any station with more than one pair of feeders.

Especially useless in such a case is a machine that gives a rise in potential with an increase in the current, as that requires throwing in an unnecessary amount of resistance into any feeder that happens at the moment to be not very heavily loaded. In order to detect any ground the following device is a very common one:—Two lamps are connected in series between the two poles, and some point between is grounded. Then, if there is a dead ground, one of the lamps—which, of course, were before burning very low, at about 55 instead of 100—begins now to burn brightly, showing that there must be a ground on some connection to the other pole. In order to call the engineer's attention to this, and at the same time to serve as a more exact method of detecting a ground, the wire leading to the ground is passed through an electro-magnet that will ring on the passage of $\frac{1}{100}$ of an ampere, or detect an insulation resistance of 10,000 ohms. When they find that they have a ground somewhere, they have an arrangement so that by grounding the other pole of the machine, and by using a succession of different sized fuses, they can burn out the fuse of that particular branch on which the ground has taken place, and when the man in whose house it was complains that his fuse was blown out they know where the ground was.

The instruments used in the stations are, of course, the same as must be used everywhere, ammeters and voltmeters. The ammeters used usually make no pretence whatever to accuracy, and are graduated, not to amperes but lamps; so that the engineer reads off directly the number of lamps there are burning. In large central stations they have only one ammeter to each machine, so that the engineer can tell when his load has become heavy enough to throw in another machine. But in a small installation for lighting perhaps one large building or block of buildings, with only one or two dynamos besides the reserve, they have a current indicator on every branch that leads out from the switch-board. As they run their arc lights there usually two in series and each pair parallel to incandescent lamps on 100-volt circuits, that requires a little extra resistance to each lamp, so they usually run a separate circuit of iron or German silver wire from the switch-board to each pair of arc lights. As each one of these circuits has its own current indicator a station of that size will sometimes run from 15 to 20 current indicators, by means of which, however, the engineer can tell at a glance whether his lamps are all burning or not. But the thing that the engineer has to watch most carefully is his voltmeter. Gas being so much cheaper over there it is very much more difficult for electric lighting to compete with gas than it is here; so that it is only by producing an absolutely perfect light that they are able to find customers who are willing to pay the extra cost of electric lighting. Each machine has its voltmeter, and each feeder, has a return wire from the junction box with either a voltmeter that can be put in connection with each feeder in turn or else one voltmeter for each.

These are all carefully standardised by comparison with the Siemens' torsion galvanometer, which will read, when used with care, to within one half of 1 per cent.

Usually there is a voltmeter connected to the junction box of each feeder, and the voltmeter itself is arranged with an electro-magnetic bell attachment, so that an alarm is given when the potential varies over 1 per cent. from the normal.

As all electric light wires are underground it may be interesting to know how their cables are laid. In this department, as in so many others, Siemens and Halske have a practical monopoly. The cable they manufacture for the German Edison Company of Berlin consists of the necessary number of strands, and if of a large size, such as they use for their feeders, an additional wire is put in separately insulated from the rest, for getting the potential at the ends of the feeders. These are then added together in some insulating compound. Then by a patent process of their own this is encased in lead pipe.

In order to prevent the lead pipe from corroding it is then covered with hemp and soaked in asphalte. Then to prevent this covering

Digitized by Google

or the lead pipe from getting damaged while digging up the streets for any purpose, the whole thing is then covered with a heavp strip of iron riband. Then, as a still further precaution, under all street crossings they lay old iron pipes, and draw this cable through them. Such a method has the further advantage that it does not necessitate closing the street either during the first laying of the cable or during subsequent repairs.

As you see from all this the laying of a system of underground cables as it is done there is a very expensive matter, so that the plan of laying it out with the different sizes to be used in the different streets has to be worked out with the greatest accuracy, especially where the demands for absolute constancy of light are as imperative as they are in Berlin, for instance. In order to do this a working model of the entire plant is made, consisting of a wooden frame or table, on which are marked off on a large scale the streets of that part of the city which they propose to light. The location of the central station is then decided upon, and marked down on the plan. Two wires are then run from a small battery to this point to represent the two poles of the station. Starting from here the whole plant is put in in miniature, thus covering the table with a double network of wires, representing the positive and negative lines, and separated from each other on the table by blocks of wood. Resistances corresponding to the different numbers of lamps are put in, and all the necessary experiments can be made to determine the size and location of the feeders. In order to determine the drop in potential from the central station to any given point, all that it is necessary to do is to join the positive and negative wires that we have on the table by means of a resistance corresponding to the number of lamps that are to be used, and then with a differential galvanometer, one branch of which receives its current from the battery representing the central station, and the other from the point at which the fall is to be determined, the fall in volts can be very easily determined.

In this way, for instance, can be determined better than by any calculation how many and how large feeders are necessary in any particular locality, in order that the potential shall not vary more than 1 per cent. or any other given amount, when 100 or 200 or 300 or any other number of lamps are suddenly thrown off or on, in the immediate vicinity. Thus, for instance, the two Royal theatres in Berlin are lighted from the two central stations of the German Edison Company, and it frequently must happen that all the lamps on both stages are thrown off or on at once, but it is impossible to detect so much as a waver in the light of the other lamps in the theatre, or in other buildings in the neighbourhood. This working model is always kept, and when additions have to be made, they are first tried on that small scale, in order to see what readjustments must be made to make the additions without interfering with the original plant.

The electricity being thus brought to your house, the next question is, how are you going to pay for it? Formerly the Edison zinc meters were used, but now they use almost entirely the so-called Aron's clock, a meter that was first suggested, I believe, by Prof. Perry, of England, but first put in a practical form by Aron. It consists simply of a pendulum clock, where the pendulum is a steel magnet. Behind or under this magnet is placed a coil of one or more turns of wire of very low resistance, through which the entire current that is to be measured is passed. The effect of a current passing through this coil is of course to retard the rate of the clock, if the current be going one way, or make the clock go faster if the current is going the other way. In practice the coil is always wound so as to make the clock gain, as that is found to give the best results.

The gain is a very decided one, so that any slight irregularity in the natural rate of the clock would not affect the result. For instance, in a clock intended to be used for 30 lamps, 1,000 lamp-hours will produce a gain of two hours. Supposing a man who has this 30-lamp clock to burn in reality only 15 on an average every evening, then in 66 hours the clock will have gained two hours. At the rate of five hours of an evening he would have a gain of two hours for his clock in 13 days, or a gain of about 10 minutes a day burning only half his lamps, and these clocks are warranted not to vary one half-minute per month when not under the influence of the current.

The lamps used there are suubstantially the same as those used here. They are made perhaps with more care and tested with more accuracy than is usual in this country, so that in a series of experiments on incandescent lamps made in the Polytechnic Institute in Berlin the Siemens lamps were found to come up to candle-power better when burning at the normal potential, and to have a longer life and a much better efficiency than the American lamps, though I suspect one reason was that the American lamps were not of the most recent manufacture.

In reply to a question put to him as to the nature of the contracts made for electric lighting in Germany and the method of calculating the cost, Mr. Parsons said that the number of lamps was not the basis for such undertakings, but rather the amount of illumination required. Thus, say a certain room had to be illuminated, the number of lamps would not be considered, but the meter candle-power illumination. This would vary from 8 or 10 meter candle-power for street lighting up to 50-meter candle-power, which gives a light by which one can read as well as by daylight, which has been found to be about 300-meter candle-power.

As to the running of dynamos, Mr. Parsons said machines up to any capacity whatever were always run in parallel. After one machine was run up to its full load then another machine would he started up, then the machines are thrown into multiple and gradually absorb the lights of the two; by this means an extra battery of lamps is saved. Not only are the machines run in multiple, but in Berlin the two central stations are run in multiple. They frequently use machines of different sizes.

In reply to another question, Mr. Parsons said that the potential was always maintained by hand, except in isolated installations where the machines being compounded they give very good results without hand regulation.

Asked if high-potential systems were used, Mr. Parsons said: There are very few plants in Germany that are run on what would be considered in America as a high potential. Electric lighting over there is confined almost exclusively to cities, where all wires are required to be laid underground, so that in addition to the natural cautiousness of the Germans about allowing such high potentials in their streets, there is the difficulty to encounter of making a successful insulation for high-potential currents that will last for any length of time underground without giving trouble. In Berlin the Khotinsky system is considered to use a rather high potential because they use a 150-volt incandescent lamp, and when they use arc lights put three in series. The station in Berlin run on this system was particularly interesting, as they used accumulators in addition to their dynamos, using only the accumulators for a light load and throwing on the dynamos as the load becomes heavier. Siemens and Halske made a long series of experiments with accumulators; but they found that they varied so much that they have not been able to do much with them.

PARLIAMENTARY NOTICES UNDER THE ELECTRIC LIGHTING ACTS.

Notification has been given in the *London Gazette* by several companies of intended applications to the Board of Trade, on or before the 21st inst., for Provisional Orders under the Electric Lighting Acts, 1882 and 1888. From the following summary of the various notifications it will be observed that, if the powers sought for be granted and acted upon, the electric light will soon be introduced on a commercial scale throughout London and the suburbs. Four notices are given by the Metropolitan Electric Supply Company (Limited), and two by the Chelsea Electricity Supply Company (Limited). Some of the notices, it will be seen, constitute competing schemes. The orders to be applied for outside the metropolitan area relate to Birmingham, Liverpool, Swansea, Brighton, Hove, and Dublin. In all cases there is great similarity in the powers sought for, which, generally, are for enabling the applicants to produce and sell the electric light; to erect and provide the necessary stations, engines, and works; to lay the wires, pipes, &c., for the supply; to break up the streets for the purpose; and to levy rates, &c.

The Metropolitan Electric Supply Company (Limited), of Winchester House, Old Broad-street. E.C., notify their intention of applying for four Provisional Orders for supplying—1. North London; 2. South London; 3. West London; and 4. Mid-London. By the first-mentioned order they ask for powers "to produce, store, supply, sell, and distribute electricity for public and private purposes" within the following area:—St. James and St. John, Clerkenwell; St. Mary, Islington; and St. Pancras and St. John, Hampstead. Authority is sought by the company to construct and maintain within the area of supply such central and other stations as may be necessary from time to time for the generation, storage, supply, and distribution of electricity and electric currents, together with all buildings, engines, and apparatus necessary or convenient for the purpose, and to lay down, maintain, &c., "electric lines, wires, conductors, mains, pipes, and other apparatus and works for the supply and distribution of electricity and electric currents in, over, along, or across all the streets, bridges, squares, courts, alleys, highways, lanes, roads, thoroughfares, and public passages and places within the area of supply." The order will contain clauses empowering the company to "break up and interfere with" streets, &c., within the area of supply, authorising them to purchase by agreement "lands and houses, and also patent rights and licenses or authorities for the use of inventions or protected processes relative to the production, supply, and distribution of electricity, and to manufacture, purchase, hire, and supply meters, lamps, appliances, machinery, and apparatus, for and in relation thereto;" authorising the company to enter into agreements with local authorities, companies, and persons as to the supply of electricity and the works required; empowering the company to make charges and levy rates for supplying electricity; defining and limiting the prices to be charged; exempting the company, under specified circumstances, from the obligation to supply electricity; and providing, if deemed necessary or expedient, for the subdivision of the area of supply. By this Provisional Order relating to South London the company seek similar powers in connection with the

Digitized by Google

supply of electricity to Lambeth, otherwise St. Mary, Lambeth ; Christchurch, St. Saviour (including the Liberty of the Clink) ; Streatham, otherwise St. Leonard's, Streatham, and Clapham. The "parishes and places" in West London which the company seek to supply with electricity under similar conditions are St. Marylebone, Paddington, and St. Mary Abbot (otherwise St. Mary Abbotts), Kensington. In their Provisional Order relating to Mid-London the company seek for powers to supply the city of London and the Liberties thereof, and the following parishes and places in the county of Middlesex, viz. :—St. John the Evangelist and St. Margaret, Westminster ; St. George, Hanover-square ; St. Giles-in-the-Fields, St. George, Bloomsbury ; St. Andrew, Holborn-above-Bars ; St. George the Martyr, St. Sepulchre, Saffron-hill, Hatton-garden, Ely-rents, and Ely-place, the Liberty of Glasshouse-yard, St. Anne, Soho ; St. Paul, Covent-garden ; St. John the Baptist, Savoy, or precinct of the Savoy ; St. Mary-le-Strand, St. Clement Danes, and the Liberty of the Rolls, together with the extra-parochial places known as the Charter House, Gray's Inn, Lincoln's Inn, Staple Inn, Furnival's Inn, and the Close of the Collegiate Church of St. Peter.

The London Electric Supply Corporation (Limited), whose registered office is at 3, Adelphi-terrace, Strand, ask for powers to produce, store, supply, and sell "electricity, electric current, and other like agency" for public and private purposes in the following area :—St. Martin-in-the-Fields, St. Margaret and St. John (United) Westminster, St. James, Westminster ; St. George, Hanover-square ; Chelsea ; St. Mary Abbotts, Kensington ; Paddington ; St. Marylebone ; St. John, Hampstead ; St. Pancras ; St. Mary, Islington ; St. James and St. John (United), Clerkenwell ; St. Leonard, Shoreditch ; St. Luke ; in the Strand district, the St. Giles district, the Holborn district, the city of London, the Whitechapel district, and the parish of St. George's-in-the-East ; in the extra-parochial places of Lincoln's Inn, Gray's Inn, the Inner and Middle Temple ; in the district of Greenwich ; in the parishes of St. Mary, Rotherhithe ; St. Mary, Lambeth ; St. Mary, Newington ; St. George-the-Martyr, Southwark ; and St. Mary, Bermondsey ; the district of St. Olave, and the district of St. Saviour and Christ Church. The works proposed to be "constructed, used, and maintained" are described generally as follows :—A central station, or central stations, at which electricity will be generated or collected, and a system of distributing stations and mains by which electricity will be conveyed and distributed from the central station or stations throughout the area of the supply. In other clauses the necessary powers were sought as to the acquisition of lands, arrangements with local authorities, interference with streets, &c., in the area of supply ; exemption from the Metropolitan Building Acts, and the levying of rates and charges.

The Electrical Power Storage Company (Limited), of 4, Great Winchester-street, E.C., intend to apply for a Provisional Order, authorising them to produce, store and supply electricity for all or some of the public and private purposes defined by the Acts of 1882 and 1888, within the following areas :—In the parish of St. Martin's-in-the-Fields :—West Strand, Cecil-street, Salisbury-street, Ivy Bridge-lane, Adam-street, Adelphi-terrace, Robert-street, John-street, James-street, William-street, Durham-street, Buckingham-street, York-place, George-court, York-buildings, York-terrace, Villiers-street, Victoria Embankment, Brewer's-lane, Northumberland-passage, Craven-street, Northumberland-street, Northumberland-avenue, Great Scotland-yard, Charing Cross, Craig's-court, Duncannon-street, St. Martin's-place, Chandos-street, St. Martin's-mews, Adelaide-street, King William-street, Exeter-street, Burleigh-street, Whitehall-place, Middle Scotland-yard, Whitehall-yard, Eagle-court. In the district of the Strand Board of Works :—The Strand, Thanet-place, Palsgrave-place, Devereux-court, Essex-street, Little Essex-street, Milford-lane, Water-street, Arundel-street, Howard-street, Norfolk-street, Surrey-street, Strand-lane, the Approach, Victoria Embankment, Wellington-street, Savoy-street, Savoy-hill, Church-row, Beaufort-buildings, Herbert's-passage, Fountain-court, Somerset-street, Carting-lane, Cecil-street, Burleigh-street, Exeter-street, Wellington-street, Catherine-street, Helmet-court, Angel-court, White Hart-street, New Church-court, Drury-lane, Feather's-court, George-yard, Windsor-court, Denham-court, Drury-court, Newcastle-street, Holywell-street, Wych-street. Power is asked enabling the company to purchase or lease land, and to erect and work thereon all necessary stations, engines, &c. ; and the company also seek to be empowered to "manufacture, hire, sell, and let all necessary machines, lamps, accumulators, meters, fittings, plant, machinery, and other matters or things" required for the purposes of the order, and "to acquire, work, and use patents and licenses for patents for the making, producing, controlling and measuring, or otherwise, relating to the supply of electricity."

The House-to-House Electric Light Supply Company (Limited), whose registered office is at 117, Bishopsgate-street Within, E.C., will apply for a Provisional Order to supply electricity for public and private purposes for such period as shall be prescribed within the following area :—All the streets and thoroughfares in the parish of St. Mary Abbotts, Kensington (other than High-street, from its eastern end as far west as the Kensington High-street Railway Station, King-street, Church-street, Ball-street, Kensington-square, Young-street, James-place, Charles-street, Kensington-court, Prince of Wales'-terrace, Victoria-road, Cambridge-place, Albert-place, Douro-place, St. Alban's-road, De Vere-gardens, Palace-gate, Canning-place, Hyde Park-gate, and Kensington-gate), and also the following private streets : — Adam and Eve-mews, Adrian-mews, Albert-mews, Alveston-mews, Ashburn-mews, Atherstone-mews, Avenue (The), Barkstone-gardens, Bolton-mews, Bolton Studios, Bramham-gardens, Bremner-road, Canning-mews, Chelsea-grove, Cleveland Terrace-gardens, Cluny-mews, Collingham-gardens (west of Collingham-road), Courtfield-mews, Cranley-mews, De Vere-mews, Evelyn-terrace, Evelyn-gardens, Egerton-gardens, Elm-mews, Farnell-mews, Faucett-mews, Gaspar-mews, Grenville-mews, Harrington-mews, Hyde Park-gate, Holmes-place, Hollywood-mews, Jay-mews, Kramer-mews, Kensington-crescent, Kensington-gate, Kingsley-mews, Lexham-mews, Ligon-mews, Logan-mews, Nevern-square, Old Manor-yard, Onslow-mews, Ovington-mews, Dennant-mews, Pembroke-place West, Philbeach-gardens (Warwick-road), Queensbury-place, Queensbury-mews, Radley-mews, Redcliffe-mews, Roland-gardens, Shaftesbury-mews, Stratford-avenue, Sydney-mews, Tarn-mews, Victoria Grove-mews, Wynnstay-gardens, Abbey-road, Airlie-gardens (north side), Albion-place, Bassett-road (west of St. Mark's-road), Bransford-street, Branstone-street, Campden House-mews, Colville-mansions, Colville-mews, Colville Square-mews, Drayson-mews, Edinburgh-road, Fowell-street, Golden-mews, Hansard-mews, Hayden's-mews, High Lever-road, Lambton-mews, Linden-gardens, Linden-mews, Lorne-gardens, Murchison-mews, Observatory-gardens, Oxford-gardens (west of St. Mark's-road), Oxford-mews, Palace Gardens-mews, Railway-mews, Roseland-place, Ruston-mews, St. Helen's-gardens, Silvester-mews.

The Provisional Order for which the Westminster Electric Supply Corporation (Limited), of Victoria-mansions, Victoria-street, Westminster, will apply seeks for powers authorising the company to supply electricity for public and private purposes in the Parishes of St. Margaret and St. John the Evangelist, in the City and Liberties of Westminster ; in the Board of Works district for the Strand ; in the Parish of St. George, Hanover-square, in the City and Liberties of Westminster ; in the Parish of St. Peter's, in the City and Liberties of Westminster ; in the Parish of St. Martin's-in-the-Fields, in the City and Liberties of Westminster ; in the Parish of St. James's, Piccadilly, in the City and Liberties of Westminster.

The Chelsea Electricity Supply Company (Limited) will ask for powers to produce, store and supply electricity within that part of the Parish of St. George, Hanover-square, which is to the east of the boundary of Chelsea parish. Among the streets, &c., more particularly proposed to be supplied (but not to the exclusion of the other streets and places within the said area) are Belgrave-square, Buckingham Palace-road (part of) ; Chapel-street, Chesham-place, Chesham-street, Chelsea Bridge-road (part of) ; Chester-place, Chester-square, Chester-street, Chester-street (west) ; Chester-terrace, Eaton-place, Eaton-place (West) ; Eaton-square, Eaton-terrace, Ebury-street (part of) ; Eccleston-street, Elizabeth-street, Grosvenor-place, Grosvenor-crescent, Halkin-street, Halkin-street (west) ; Hobart-place, Knightsbridge (part of) ; Lower Belgrave-street, Lower Grosvenor-gardens, Lowndes-place, Lowndes-street (part of) ; Lyall-street, Motcombe-street, Pimlico road (part of) ; Pont-street (part of) ; Upper Belgrave-street, Upper Eccleston-street, Upper Ebury-street, Upper Grosvenor-gardens, Westbourne-place, Wilton-crescent, Wilton-place, Wilton-street. Similar powers are asked by this company in another Order for supplying that part of the parish of St. Mary Abbotts, Kensington, which lies south of the Brompton, Old Brompton, and Richmond roads, west of Ovington-gardens, and is bounded on the south by the northern boundary of the parish of Chelsea. The notice states that "it is more particularly proposed to place electric lines and works in, over, and along the whole or portions of the following streets and places" (but not to the exclusion of the other streets and places within the said area) :—Boltons, Brompton-crescent, Brompton-road (part of), Cathcart-road, Cranley-gardens, Cranley-place (1), Cranley-place (2), Drayton-gardens, Egerton-gardens, Egerton-gardens-mews, Exhibition-road (part of), Elm-place, Finborough-road, Foules-terrace, Fulham-road, Gilston-road, Harcourt-terrace, Harley-gardens, Highfield-road, Hollywood-grove, Michael's-grove, North-terrace, Old Brompton-road, Onslow-crescent, Onslow-gardens, Onslow-houses, Onslow-square, Ovington-gardens, Ovington-square, Pelham-crescent, Pelham-place, Redcliffe-gardens, Redcliffe-road, Redcliffe-square, Redcliffe-street, Richmond-road (part of), Roland-gardens, Roland-houses, Selwood-place, Seymour-place, Sumner-terrace, Sumner-place, Sydney-place, Thurloe-square, Tregunter-grove, Tregunter-road.

The Kensington and Knightsbridge Electric Lighting Company (Limited), or the Kensington Court Electric Lighting Company (Limited), or both of them, whose offices are in High-street, Kensington, will apply for an order to produce, store, supply, and sell electricity, electric current, "and other like agency" for public and private purposes, within the parish of Saint Mary Abbotts, Kensington, and so much of the parish of Saint Margaret, Westminster, as lies to the west of the parish of St. George, Hanover-square.

The Notting Hill Electric Lighting Company (Limited), of 20, Great Winchester-street, E.C., will ask in the Order for which they intend to apply, for powers to produce, store, and sell electricity in the parish of St. Mary Abbotts, Kensington.

The Brighton Electric Supply Company (Limited), of 47, Gloucester-road, Brighton, will ask for an Order to supply electricity, for public and private purposes, in the borough of Brighton, the parish of Preston, and in the town of Hove.

The Liverpool Electric Supply Company (Limited), of 1, Crosshall-street, Liverpool, in the Order for which they notify their intention of applying will ask for powers "to produce, supply, and store electricity for lighting and other purposes" in the city. The area of supply is described as so much of the city and parish of Liverpool as is surrounded by a line drawn from the bottom of Chapel-street, up that street, thence along Oldhall-street, Great Howard-street, Leeds-street, Vauxhall-road, Midghall-street, Standish-street, North-street, Dale-street, Byrom-street, Clayton-street, Mill-lane, Islington, Norton-street, London-road, Anson-street, Pembroke-place, Ashton-street Brownlow Hill, Bedford-street North, the north and east sides of Abercromby-square, Chatham-street, Falkner-street, Grove-street, Huskisson-street, Hope-street, Upper Duke-street, Duke-street, Hanover-street, the south side of Canning-place, Strand-street, Back Goree to the bottom of Chapel-street, including in all cases the houses and buildings on both sides of the streets and places above mentioned.

Application will be made by Messrs. Arthur Chamberlain and George Hookham, of New Bartholomew-street, Birmingham, for an Order to supply electricity for all public and private purposes in the borough of Birmingham, and with such object to break up public and private streets, railways, tramways, and other places in the borough, and to erect, construct, lay

Digitized by Google

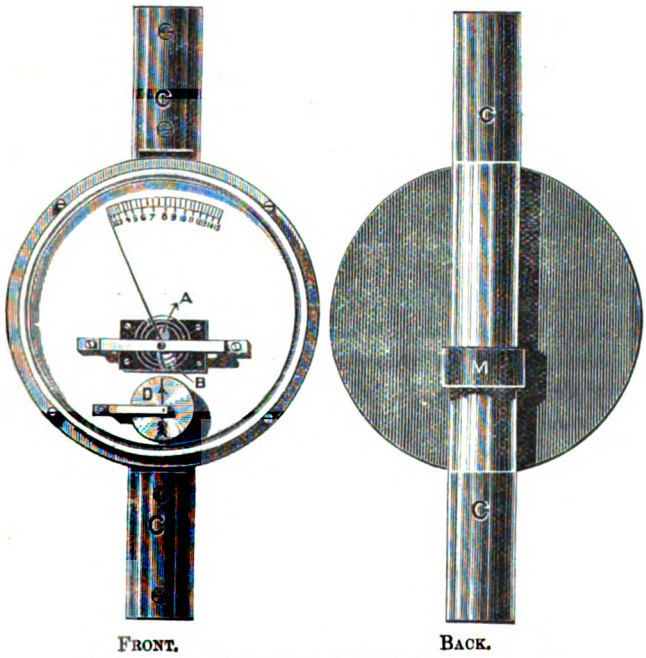
down, provide, and maintain mains, wires, and other apparatus and works; to acquire land and other rights, and to supply lamps, meters, and fittings. The notice states the area of supply within which it is proposed that the provisions of the Order shall be in force and have effect is the whole of the said borough of Birmingham, as constituted at the date of the proposed Order, but (subject to powers and conditions of extension at the instance of the undertakers, or the local authority to be inserted in the proposed Order) the area to be compulsorily supplied within three years of the date of the Order shall be so much of the borough of Birmingham as lies between the line formed by the following streets, or parts of streets, viz.:—From the junction of Edmund-street and Easy-row along Edmund-street to its junction with Livery-street, thence along Livery-street to its junction with Colmore-row, along Colmore-row to its junction with Bull-street, along Bull-street to its junction with the Minories, along the Minories to its junction with the Old-square, thence round the Old-square to the corner of the Upper Priory, thence continuing round the Old-square, down Corporation-street to its junction with Lawrence-street, thence back along Corporation-street to its junction with Bull-street, along Bull-street to its junction with Albert-street, along Albert-street to its junction with Fazeley-street, along Fazeley-street to its junction with New Canal-street, along New Canal-street to its junction with Bordesley-street, along Bordesley-street to its junction with Park-street, along Park-street to its junction with Paternoster-row, along Paternoster-row to its junction with Moor-street, along Moor-street to its junction with Carr's-lane, along Carr's-lane to its junction with High-street, along High-street and down the Bull Ring to its junction with Moor-street, thence across the Bull Ring and along Bell-street to its junction with Worcester-street, thence along Worcester-street to its junction with New-street, along New-street to its junction with Paradise-street, along Paradise-street to its junction with Easy-row, and thence along Easy-row to its junction with Edmund-street.

Application will be made by the Corporation of Swansea to produce, store, and supply electricity within the borough; to manufacture, purchase, hire, sell, and let all necessary machines, lamps, accumulators, meters, fittings, plant, machinery, and other matters or things required for the purposes of the Order; and to acquire, work, and use patents for the producing, storing, controlling, and measuring, or otherwise relating to the supply of electricity.

The Corporation of Dublin will apply for powers to supply electricity for all public and private purposes within the city.

AMMETER FOR LARGE CURRENTS.

The instrument illustrated below is being introduced by Messrs. Paterson and Cooper for the measurement of large currents, and contains several valuable improvements made by Mr. S. Joyce, one of their electrical staff. It is of the electro-magnet type, and consists of a round bar of copper, C C, nearly encircled by a split



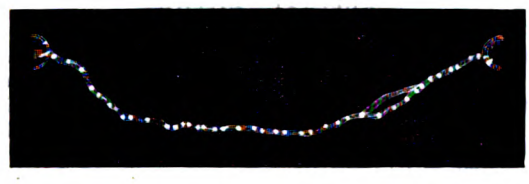
FRONT. BACK.

Paterson and Cooper's Ammeter for Large Currents.

soft iron ring, M. On the ring on opposite sides of the gap are fixed pole-pieces, between which is pivoted the soft iron needle A. The needle is mounted on an axle working in jewelled centres, and is maintained at zero when no current passes by a spiral spring, as shown. The deflection is indicated by a pointer, which is balanced by a counterweight, B. When the current passes through the copper bar the ring is magnetised and the needle is deflected. The dial is marked proportionally to the current, the instrument illustrated measuring 1,500 amperes. The dial and the working parts are screwed directly on to the copper bar, the construction admitting of great strength and durability, since no insulation is employed. The small disc D has a magnetised needle fixed at its back, so as to indicate the direction of the current. The accuracy of the indications is unaffected by all ordinary positions of the leads to and from the instrument, it being found that when a return is passed down at the back parallel to C C, and within one inch of the iron ring, the deflection is altered by only one per cent. Being an electro-magnet instrument there is no recalibration required, nor is there any perceptible error due to residual magnetism. It is made in sizes from 300 to 2,500 amperes or more, and the calibration is effected direct by comparison with one of Sir W. Thomson's kilo-ampere balances.

THE DURATION OF LIGHTING FLASHES.

It is well known that the lighting flash, or the spark between the terminals of an influence machine, exists for so short an interval of time as to be beyond measurement by any ordinary means. But notwithstanding the acceptance of this knowledge, the peculiarities of some of the flashes photographed have been supposed to be due to the camera, or the sensitive plate, being at the time in a state of vibration. To test this line of thought, Mr. James Wimshurst has made a dark slide for his camera, in which is fitted a train of clockwork carrying a disc, upon which is an arrangement for holding the sensitive plate. When all is com-



plete for photographing a flash, the clockwork is wound up, the sensitive plate then rapidly acquires great velocity, which at the maximum reaches 2,500 revolutions per minute, and with the plate rotating at this speed the spark is photographed. The annexed engraving is from a photograph taken under these circumstances; as will be seen, it in no way indicates movement in the sensitive plate, for the photograph throughout its length is as sharp and as clear as though the plate had been at rest. The experiment is interesting, for it not only shows the infinitely short existence of the spark, but it also shows that chemical change in the sensitive film takes place in an equally minute interval of time.—*Engineering.*

MEETINGS OF SCIENTIFIC SOCIETIES, &c.

SATURDAY, December 8th.

PHYSICAL SOCIETY.

3 p.m. "On Some Facts Connected with Systems of Scientific Units of Measurements." By Mr. T. H. BLAKESLEY.

MONDAY, December 10th.

SOCIETY OF ARTS.

8 p.m. Cantor Lecture. "Light and Colour." By Capt. W. de W. ABNEY, C.B., F.R.S. (Third Lecture.)

TUESDAY, December 11th.

INSTITUTION OF CIVIL ENGINEERS.

8 p.m. Discussion on Mr. J. Oliver Arnold's Paper on "The Influence of Chemical Composition on the Strength of Bessemer Steel Tyres."

ROYAL VICTORIA HALL.

8:30 p.m. Lecture, "Limestone Rocks and their History." By Mr. EDWARD WETHERED, F.R.S.

WEDNESDAY, December 12th.

SOCIETY OF ARTS.

8 p.m. Ordinary Meeting. "Explosives." By W. H. DEERING F.C.S.

THURSDAY, December 13th.

SOCIETY OF TELEGRAPH ENGINEERS.

8 p.m. Annual General Meeting. Election of Council. Conclusion of the Discussion on Mr. HENRY EDMUNDS' Paper "On a System of Electrical Distribution."

FRIDAY, December 14th.

INSTITUTION OF CIVIL ENGINEERS.

7:30 p.m. Students' Meeting. "The 26-Knot Spanish Torpedo-Boat 'Ariéte.'" By JULIAN KING-SALTER, Stud. Inst. C.E.

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny.
Editorial, Publishing and Printing Offices:

No. 1, SALISBURY COURT, FLEET STREET, LONDON, E.C.

Telephone No. 2714.

All Communications to be addressed to "The Electrician," 1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to "The Electrician."

All letters intended for insertion in "The Electrician," or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.

"The Electrician" is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.

"The Electrician" is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.

SPECIAL NOTICE.

Owing to the increase in the number of pages of "The Electrician," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.	6 months.	12 months.
For Foreign Parts and Colonies:—	s. d.	s. d.	s. d.
Within Postal Union	6 6	12 6	24 0
„ Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	14 6	28 0
The rates for the United Kingdom remain as follows:—	5 0	10 0	19 6

TO ADVERTISERS.

"The Electrician" offers exceptional advantages to Advertisers. **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

Trade Advertisements *intended for the current issue must be handed in not later than First Post on Thursday morning.*

Small Prepaid Advertisements *(for Rates see page xi.) are accepted up to 4:30 p.m. on Thursday.*

TECHNICAL PRINTING.

"The Electrician" Printing and Publishing Company (Limited) *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

The Electricians' Directory.

Royal 8vo. Cloth Boards, 3s. 6d., post free 4s.

At the commencement of each year is issued The Electricians' Directory and Handbook. *The Directory was established in 1888, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

THE DIRECTORY FOR 1889 IS IN PREPARATION,

And new names and addresses are now being received,

"THE ELECTRICAL WORLD" IN THE UNITED KINGDOM.

Arrangements have been made by which "The Electrical World" of New York can be obtained from "The Electrician" Office, 1, Salisbury-court, Fleet-street, London, E.C.

The Rate of Subscription (payable in advance), including postage, is **£1 1s. 0d.** *per annum to this Country and Abroad.*

Single Copies of "The Electrical World" can also be obtained, **price 6d. each.**

The Rates for Advertisements in "The Electrical World" of New York can be obtained on application to "The Electrician" Printing and Publishing Company, Limited, as above.

VOLUME XXI. OF "THE ELECTRICIAN."

Volume XXI. of "The Electrician" is NOW READY,

Price 12/6, post free 13/6.

Cases for Binding Volume XXI. are Now Ready, Price Two Shillings Post Free, Two Shillings and Threepence.

ELECTRIC TRACTION.

The report presented at the meeting of the Blackpool Electric Tramway Company (which was printed in our last issue) may be held to prove that this undertaking has finally emerged from the experimental stage and has developed into a commercially prosperous concern. An increased traffic of nearly 100,000 passengers, making a total of over 700,000 for the year, with a mileage of 90,000 miles, a dividend of 4 per cent. on a paid up capital of £20,000, and a sum of £1,000 carried to the reserve fund, are all unmistakable evidences of practical success, and give every reasonable promise of a prosperous future. But whilst congratulating Mr. Holroyd Smith, the directors, and shareholders on this result, we would take occasion to emphasise the fact that it has far more than a local significance; indeed, we hold that it has, or should have, a most important bearing on the future of electric traction in this country. Its importance arises, as all who are conversant with the circumstances will be aware, from the fact that the Blackpool line is one of the very few existing lines upon which the conduit system is employed. With the exception of the Gravesend line, which the Series Traction Syndicate is now constructing,

Digitized by Google

no other conduit line exists in this country, and but very few—not more than five or six to our knowledge—in America.

The two or three remaining lines in this country, and the majority of those on the Continent, are worked with currents taken off either from one of the ordinary rails, or, more often, from a special third rail; and it is a striking fact that, notwithstanding all that has been said and done in respect of battery traction, we cannot at present point to a single existing illustration of its use in this country. In Brussels, after extensive trials of the Julien system, it has not led to results of a satisfactory character; at Lisbon the same system has just been replaced by that useful animal the mule. In Paris it is true that a line of battery cars has been running between the Porte Maillot and L'Etoile during the last few weeks, but for too short a time to judge of the ultimate result. In Germany and Austria we are unable to recall a single instance of the use of battery cars. In America, so far as our information extends, there are at present three such lines—still, however, in the experimental stage (as against some 80 or 90 worked by overhead lines); whilst in London we must not forget to mention that the Electric Traction Company will shortly have six trams running on the line between Barking and Canning Town. At Birmingham also we have recently mentioned some trials which, so far as the mere working of the car is concerned, have been quite successful. If we finally add that some important orders have recently been fulfilled for Australia, we shall have pretty nearly exhausted the existing evidences of the commercial feasibility of the method in question.

In saying all this, we wish at the same time to make it perfectly clear that we by no means despair of the future of battery traction. We have recently spoken of this as the *ideal* solution of the problem, provided only that we can obtain the ideal cell. And although that may be, and almost certainly is, an unrealisable standard of perfection, still we do look forward to the time when the battery will have arrived at such a stage of development as to admit of its utilisation for the purposes of electric traction with that degree of confidence which alone entitles a scheme to take rank as a commercial as distinguished from an experimental process. Meanwhile, facts are facts, and until we see the balance-sheet of a company in which a dividend has been paid on the results of this method of working, we must decline to regard it as standing upon the same commercial footing as the other systems to which we have referred.

Seeing the unquestionable and much higher degree of success which batteries designed for lighting have now attained, it may be useful to inquire why this is so. The inferiority of the traction battery is partly accounted for by lack of experience. The experience gained in lighting is at least a hundredfold as great; and yet it has not been until the present year of grace that the E.P.S. Company has developed a cell which may be considered as at least approximating to a final form. This is a deficiency which can only be allowed to work its own cure. Another point of more fundamental importance is to be discovered in the fact that, in order to reduce the weight of traction cells within workable limits, the current density is required to be very considerably greater than in other cases. For lighting work a current density of 1 ampere per 30 or 40 square inches of positive plates is common practice, whilst in the cases which have come under our notice for tractive purposes an output of 1 ampere per 12 to 18 square inches was usually obtained. This consideration is alone sufficient to emphasise the wide distinction between the two problems. Again, the variations in the load on the traction battery, which are necessarily so frequent and so extreme, are highly detrimental to the life of the plates, whilst this state of things is seldom or never paralleled in the case of batteries used for lighting. The weight of the cells is an objection which operates as a function of the second or third degree; for it not only demands a more substantial and, therefore, heavier car and a more powerful motor, but this in itself involves additional cells to accomplish the work, and so on, like the hare and the tortoise. So that, on the whole, we should scarcely be surprised if in the end we are led to the abandonment of lead batteries for this particular purpose. We are, nevertheless, glad to state, from facts which have recently come to our knowledge, that substantial improvements have been made in the design of lead batteries for traction work, and next week we shall probably have an opportunity of putting before our readers some results which we believe to be the best hitherto attained.

Tramway companies are very naturally averse to any innovation which involves a structural change in their lines, and there are, doubtless, many cases in which the conduit would be just as inadmissible as the overhead system so much in vogue in America. Nevertheless, the results achieved at Blackpool are full of encouragement, and where there is no fundamental objection to the introduction of this system, we feel confident that it would be accompanied by increased dividends to the shareholders. We may add that the little tramway on the Ryde Pier, which is worked on a third rail system, has been shown to cost 25 per cent. less than when horse traction was employed.

THE GEYER-BRISTOL METER FOR DIRECT AND ALTERNATING CURRENTS.*

BY PROF. WILLIAM R. GEYER.

In the meter about to be described we make use of the heating effect of the current. Electric measuring instruments depending on this heat effect are not new, as in the Cardew voltmeter we have an application which has found much favour. Here the current of greater or less strength traverses a long thin wire, heats it more or less, and the direct expansion is a measure of the current, and indirectly of electromotive force.

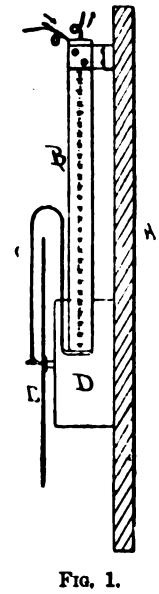

FIG. 1.

In an ammeter it is necessary to keep down the resistance, and I therefore doubt whether direct expansion can be usefully applied for this purpose; for the actual elongation of a bar of metal, even when raised through a considerable range of temperature, is very small. In the familiar compound bar we have a case where a very small actual elongation produces a relatively very great lateral displacement.

I think I shall best be able to explain to you our meter by recall-

* Read before the American Institute of Electrical Engineers, New York, Nov. 13, 1888.

Digitized by Google

ing to your minds this old device. In the simplest compound bar two strips of metal which have different coefficients of expansion are securely soldered flatwise along their entire length. Brass and steel are metals frequently employed. On heating, the brass expands more than the steel, and, in consequence, the bar bends, becoming convex on the side of the brass. When such a bar is heated by the passage of the electric current it will deflect, and this deflection may be made a measure of the current. The disadvantage of such an instrument would be that atmospheric changes of temperature would also cause deflection, so that troublesome corrections would have to be introduced.

In our meter we also use a sort of compound bar, but eliminate at once the effect of the surrounding temperature by taking metals whose coefficients of expansion are the same or sensibly equal—in fact, we take the same metal. Our first form of construction was as follows :—A wire of German silver is laid upon a strip of German silver of considerably greater cross-section and radiating surface. The wire and strip are soldered together at one end, separated for the remainder of the length by a film of mica, then tied together at frequent intervals with silk or other insulating material, and suitably supported or clamped at the unsoldered end. If now a current,

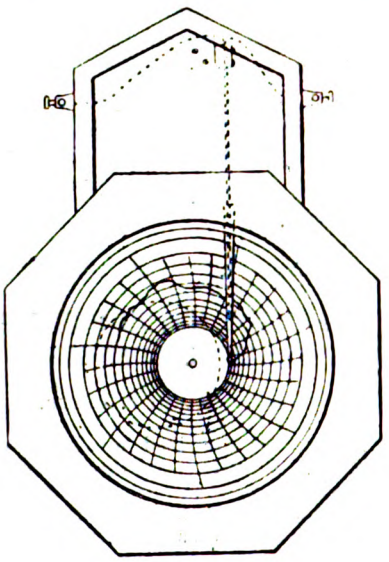

Fig. 2.

either continuous or alternating, is allowed to enter the strip at one end, it runs along its length, there enters the wire, and leaves the instrument at the other end of the wire.

For a given current the wire, on account of its greater resistance, and also on account of its smaller radiating surface, becomes hotter than the strip. In consequence of the difference of expansion the bar bends, becoming convex on the side of the smaller conductor. This combination we call a differential bar.

We would also state that inasmuch as the results obtained by the use of this instrument are due to the excess of the heating effect of an electric current upon one portion of the bar, or its equivalent, over the other, it is in a measure immaterial to the principle of the invention whether the current which produces the differences in temperature be caused to heat the two parts directly or indirectly. For example, the more expansible part, in lieu of being included directly in the circuit, may be arranged in close proximity to, but insulated from, a wire or conductor which is heated by the current. The other part or element may be in the circuit or not, but in either case formed or arranged to be less sensibly heated than the other.

It will readily be seen, however, that to heat one or both of the parts of the device in this manner would be clearly equivalent to connecting them both in series in an electric circuit. Unlike the case where magnetic action is employed, the force here available is very considerable, so that, to make the instrument self-recording, it is only necessary to attach an inking device to the free end and move in front of it a properly ruled chart. In this respect we have no difficulty whatever. My associate, Prof. Bristol, who has done the larger part of the work, has, since our first experiments, very much simplified the method of constructing the differential bar, and the one used in the instrument exhibited was made by placing a flat strip of German silver between a pair of dies which make alternate depressions and elevations along the length of the bar ; the wire, insulated with asbestos, was then slipped in the tube-like space thus formed, and the whole pressed between plates provided with grooves of the proper depth so as to leave the wire to one side of the centre line and at the same time to insure its being held firmly by the little bridges along the length of the bar. Since the bars can be constructed essentially by these two machine operations it is evident that they may be readily reproduced and at very small cost.

We have determined experimentally the best relation between the cross section of the strip and wire to give maximum deflection. We believe the instrument could readily be made integrating, but doubt the desirability of doing so. Our reason for this could probably not be better expressed than in the words of an eminent engineer, Mr. Charles E. Emery, in his Paper on "Heating Cities by Steam," before the Franklin Institute, which we quote as follows :—

"It was at first considered unfortunate that a reliable meter could not be obtained, which, like a water meter, would show by differences of reading the quantity of steam used for the interval between observations directly without calculation, and without expense of maintaining a time register at each location, and of integrating the charts afterwards. This system, however, proved a blessing in disguise. The greatest difficulty in settling with consumers lies in the fact that *employés* waste the steam. This is particularly the case during the heating season, when steam for various uses is left on continuously during nights and Sundays, thus increasing the time of consumption from, say, 60 hours a week to 168 hours. In many cases, too, the rate of consumption keeps uniform during the night as well as during the day, so that it is an easy matter to more than double the bills. The consumers at first naturally lay the blame to the steam of the steam company, but the meter charts have been the means of enabling the company to satisfy consumers when, and to what extent, the increased bills were due to mismanagement on their premises."

Substitute electricity for steam and the reasoning will apply perfectly to our case.

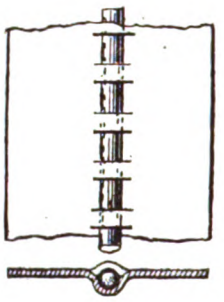

Fig. 3.

In the accompanying illustrations Fig. 1 is a general view of the differential bar, mounted in a case, with inker and recording dial. Fig. 2 is a side view of the important parts, the case being removed.

The following letters refer to the different parts :—

A, supporting framework ; B, differential bar ; C, inking pointer attached to bar ; D, clockwork moving dial ; E, revolving dial for receiving record.

Fig. 3 shows a small portion of the bar and a cross section on an enlarged scale.

LETTERS FOR LEARNERS AND UN-PROFESSIONAL READERS.

BY H. D. WILKINSON.

Section II.—Electro-Magnetic Fields.

(*Continued from page 80.*)

137. *Magnetic Susceptibility.*—As Science moves onward she draws in her train an ever-increasing number of newly-coined or adopted words and names, to each of which she assigns a definite *rôle*—that of representing with rigid exactness some new idea or phenomenon, or perhaps of being the more concise representative of some already known but hitherto undefined property of matter. Perhaps in no paths of discovery has she so far perpetuated in this manner the names of those who have worked laboriously in her cause as in electrical and allied researches, in which such famous names as Volta, Ampère, Ohm, Coulomb, Faraday, Joule, and Watt are constantly in use by those who are engaged in developing the many practical applications turning on their discoveries. It sometimes happens, however,

Digitized by Google

that science presses into her service words which have been more or less in the familiar use of common parlance. When, however, such words are "told off" to serve her, she requires that, whatever variety of garb they may choose to wear in their capacity as civilians, one distinctive uniform only must be worn when they are enlisted in her corps and on duty in her service. In other words, science requires that definite ideas shall be represented by special terms set apart exclusively for their use. As instances, we might cite such words as force, strength, mass, intensity, power, work, energy, capacity, &c., which all have considerable flexibility of meaning in ordinary use, but only one distinctive meaning in their scientific application.

The word "susceptibility," which we are about to consider, has been told off to express a state or condition of iron in which it is more or less "susceptible" of becoming magnetised under the action of electromagnetic force. In the familiar use of the word we speak of "susceptibility to pain," "susceptible of impressions," "susceptible to charms," &c., and, turning to see what Johnson says, we find he quotes a sentence from "Wotton" to illustrate its meaning as follows:—"He moulded him platonically to his own idea, delighting first in the choice of materials, because he found him *susceptible* of good form." Put into the simplest language, we may say that great or little susceptibility conveys the idea of the ease or difficulty with which an acting cause produces a corresponding effect. When the subject operated upon possesses great susceptibility a given acting cause can produce a great effect, but when it has little susceptibility the same acting cause can produce but little effect. The subject operated upon in our present case is iron, the acting cause magnetising force, and the effect the magnetisation produced. Iron is said to have a greater maximum *magnetic susceptibility* than steel, because under a given magnetising force it acquires a higher intensity of magnetisation. Also, the magnetic susceptibility of iron or steel varies according to the state of magnetisation. On applying a gradually-increasing magnetising force to iron its susceptibility is at first small, then increases very rapidly to a maximum, and then falls again almost to zero. This may be noticed in the curves already worked out.

We may now define magnetic susceptibility (usually denoted by the Greek letter κ) as the ratio between I, the intensity of magnetisation acquired, and H, the acting magnetising force, and write it

$$\kappa = \frac{I}{H}.$$

For example, taking the higher curve in the last figure it will be noticed that for a magnetising force of 10 C.-G.-S. units the magnetisation acquired is 800, and therefore the susceptibility is 80. This is at the steepest part of the curve, and is therefore the maximum susceptibility in this specimen. As the iron becomes practically "saturated" at the sharp bend of the curve the susceptibility is reduced to $\frac{1200}{30} = 40$, and at the highest magnetising force employed (170 C.-G.-S. units) it becomes very small, viz., $\frac{1330}{170} = 8$ nearly.

Prof. Ewing found the susceptibility of a specimen of very soft iron to reach up to 280, and when mechanical vibrations were applied to the same specimen while under the magnetising force its susceptibility increased to as high a value as 1,600.

One important point must be noted. Any piece of iron, the susceptibility of which is to be determined, must comply in dimensions with the condition of "endlessness" spoken of in para. 133, otherwise the exact magnetising force brought to bear upon it cannot be computed. For instance, from the lower curve in the last figure the susceptibility of that specimen of iron cannot be derived, because the dimensions of the core are such that a demagnetising force of unknown value is acting on it in addition to the force due to the coil.

138. *Further Developments of the Subject.*—Before leaving this subject we shall indicate in what direction the student may experiment with advantage. Besides the acquaintance he will gain with the subject by trying cores of different specimens of iron and steel of different dimensions, he should carry the magnetisation of some specimens through a complete phase or cycle; that is, starting by increasing the current from zero, the ordinary curve of magnetisation rises from 0 (Fig. 120). After carrying this on until the core is fairly saturated, the current is gradually reduced to zero. The curve, as we have seen, will not return to the point of origin by reason of the residual magnetism O A. Now the current in the magnetising coil is reversed, and precisely the same operation repeated—viz., gradual increase of current to fair saturation, and then decrease to zero. This brings us to the point B, the residual magnetism being O B. Now the current is reversed again, and gradually increased until the highest point in the curve is again reached. The core has then been led through a complete cycle of magnetisation. The valuable suggestion made by Mr. Sidney Evershed (*The Electrician*, Nov. 9, 1888) for eliminating the effect of the magnetising coil on the magnetometer, simultaneously with the test, by winding a few turns of the said coil backwards round the magnetometer needle at such a distance as to just neutralise its own effect, should also be taken advantage of. This would allow of seeing at once by the magnetometer deflections when the core approached saturation, and also save the time of plotting two curves.

The core having been led through a cycle of magnetisation in the manner indicated, we have a completely closed curve, the area

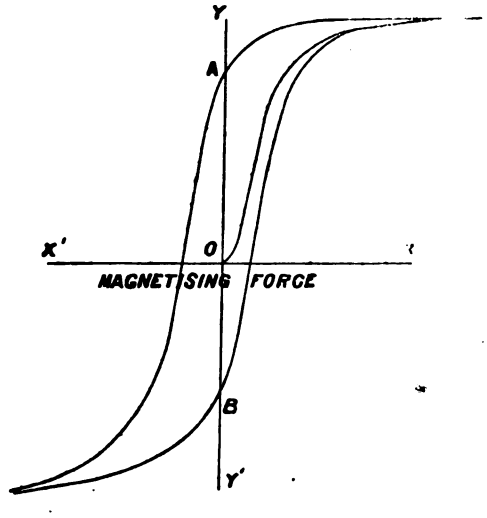

FIG. 120.

enclosed by which is proportional to the amount of work spent per unit volume of iron in conducting it through the cycle. It is evident that the cause of the cyclic curve being of this general shape and enclosing an area is due to the fact that the descending curve does not coincide with the ascending curve, and this latter fact is due to residual magnetism of the iron. In other words, the magnetisation of the iron follows at a distance or "lags behind" the magnetising force acting on it. Prof. Ewing, in a set of exhaustive experiments on this property of iron, carried out some five or six years ago at the Physical Laboratory of the University of Tokio, Japan, calls the phenomenon "*Hysteresis*," from ὑστερέω, to lag behind, and defines it as "the lagging behind of changes in magnetic intensity to changes in magnetising force" ("Researches in Magnetism," *Phil. Trans.*, 1885). In the same Paper we find the pregnant remark, "The existence of residual magnetism, when the field is reduced to zero, is, in fact, only one case of an action which occurs whenever the field is varied in any way, viz., a tendency to persistence of previous magnetic state."

In all electro-magnetic apparatus where the magnetising force is alternating in direction, or where an iron mass moves periodically through alternate fields, the iron undergoes this cyclic change, and we have the phenomenon of hysteresis. In dynamo and motor armatures, and in the cores of "transformers" or "converters" used in distributing electrical energy by the alternate current system, the loss of energy by hysteresis is an important point affecting more or less their working efficiency. It is not within the scope of the present Paper to treat of the above-

Digitized by Google

mentioned machines; the student who is pursuing the subject should, however, consult the works already referred to, in addition to which he will find the subject very clearly treated in a "Note on Magnetic Hysteresis," by Dr. J. A. Fleming (*The Electrician*, September 14, 1888). In furtherance of the subject of magnetic susceptibility, a Paper by Mr. R. Shida (*Proc.* Royal Soc., 1883), and one by Mr. A. Tanakadaté on the "Mean Intensity of Magnetism of Soft Iron Bars of Various Lengths in a Uniform Magnetic Field," read before Section A of the Bath meeting of the British Association (*The Electrician*, November 2, 1888), will be found valuable sources of information.

(To be continued.)

LEGAL INTELLIGENCE.

King, Brown and Co. v. The Anglo-American Brush Electric Light Corporation.

The action for reduction of a patent right at the instance of King, Brown and Co., Edinburgh, against the Anglo-American Brush Electric Light Corporation (Limited) was resumed in the Court of Session, Edinburgh, on Thursday, the 29th ult., when the case for the pursuers was continued. Mr. Graham Murray, Mr. Dickson, and Mr. Daniel were counsel for the pursuers; and the Dean of Faculty (Mr. Mackintosh, Q.C.), and Mr. Jameson for the defenders.

WILLIAM AUGUSTUS GORMAN, sole partner of Siebe, Gorman and Co., engineers, London, deposed that the machine, No. 29 of productions, was made in their works in 1876 or the beginning of 1877. His firm was interested in the patent, along with Mr. Varley. So far as he was concerned the patent was gone on with up to the dissolution of his partnership with Mr. Siebe in 1878. Cross-examined: As near as he could say he thought the machine was last used for any purpose, experimental or otherwise, about the end of 1877, a few months after its completion.

EDWARD FRASER MYERS, foreman with Siebe and Gorman, deposed that he constructed the machine, No. 29 of productions, in the beginning of 1877, under the instructions of Mr. Varley. As regarded the electrical arrangement, the machine was the same now as when first made. There was one circuit from the machine to the lamp, and there was a thick and a thin wire coiled round the field-magnets. The magnetic power was much increased the moment the arc was pulled. There was no secrecy about the construction or exhibition of the machine. As regarded the commutator, there was first a wooden foundation, the hub or bush, for insulating purposes. The gunmetal base pieces were permanently fixed to that wooden arrangement, and then there was a steel plate, which could be detached and romoved when it wore. It was attached by four small rivets or screws, fitted from the outside inward, the result being to preserve the cylindrical form of the commutator. He thought there had only once been an alteration of the connections.

Cross-examined: The connection between the wearing segment and the sub-segment performed the functions of both a screw and a rivet. Their idea was that the wearing segment could be removed without disturbing the sub-segment.

FREDERICK JOHN GARNISH, works manager to Siebe and Gorman, gave similar evidence as to the making and working of the machine in 1877.

DUNCAN CARMICHAEL, instrument maker in the employment of James White, optician, Glasgow, said a gentleman had called upon him recently with a copy of Varley's specification, and at his request witness made a model of the field-magnets of the machine there described. At that time he knew nothing whatever about dynamos, or of the difference between shunt, series, and compound winding.

HUGH HOLMES M'TAGGART, apprentice with Brown Brothers and Co., hydraulic engineers, Edinburgh, said he had made the model of a machine from the following instructions given to him by his employer on a piece of paper:—"You will wrap the soft-iron magnets with two insulated wires, one having larger resistance than the other. The circuit of larger resistance is always closed, and the circuit of less resistance is used for the electric light." He had no knowledge whatever of magnetism or electricity before.

GEORGE B. ANDERSON, apprentice with James White, instrument maker, Glasgow, said he began to study electrical engineering about five weeks ago. On 12th November Mr. Brown called at his workshop and gave him a copy of Varley's specification, from which he made the model produced. Nobody helped him, and he consulted no other book. He knew a little of the first principles of dynamos, but nothing about compound dynamos.

Dr. JOHN HOPKINSON, recalled, said he had opened up Varley's machine, and he found that the commutator consisted of a central boss or hub of wood of cylindrical form, to which were attached segments of brass connected to the wire of the armature. All these segments of brass were attached by means of screws to plates of iron, upon which the collecting brushes were joined together. It would be correct to describe the whole commutator as a "commutator cylindrical in form, consisting of insulating hub or body, to which are attached sub-segments placed in proper electrical connection with the general mechanism in which the commutator is employed, and wearing segments detachably attached."

Cross-examined: *Q.* Are there on this commutator metallic insulating segments such as we have in Brush's commutator?—*A.* There is this slight difference between them—in Varley's commutator the segments serve to form a connection between the two opposite brushes at the time at which the sections of the armature are insulated. In Brush's, the compensating segments insulate both the armature and the brushes from each other.

JAMES SWINBURNE, consulting engineer, and formerly manager of the Swan lamp works in Paris, the Brush-Swan lamp works in America, Hammond's incandescent lamp department, and scientific manager to Crompton and Co., deposed that he had examined the specifications of Haddon and Varley. The invention foreshadowed in Haddon's provisional specification was that of putting wearing segments on to sub-segments of the commutator. In 1878 commutators were very well known. They were arranged in various ways, but most of them had an insulating body on which the segments were placed. With reference to claims 4, 5 and 6, the use of the insulating segment T appeared to have been something for the brushes to rest on that was insulated from the rest of the commutator. The reason electrically for having a particular portion of the revolution where there was insulation between the brush and the armature was, that at that part of the revolution the coil corresponding to the segment of each side was not giving any current, and they did not want to take anything off. There was no disclosure of that in the provisional specification. The provisional specification was co-extensive with claim 2, and there was nothing about claim 4. Witness was present when Varley's machine was opened up, and he agreed with Dr. Hopkinson's description of its commutator. Brush spoke at considerable length of the advantages to be got in the process of electro-plating, but witness did not find in any part of the specification any hint of an anxiety to get a constant potential machine. Series shunt-winding was clearly described in the specification. Assuming a machine to be made in terms of that specification, and wound series shunt as there described, it would not necessarily follow that the machine would be a constant potential machine. *Q.* Is there anything in Brush's specification or drawings to give you the knowledge which is required in order to secure a constant potential machine?—*A.* No. Brush's specification would in some ways mislead. He mentioned in one place that the shunt wire might be larger than the series, or they might be of the same size, and he said the teaser might be wound in two courses. That would be misleading except for very low electromotive force. There was nothing in the drawings to show sufficiently the diameter of the wires and the other conditions necessary to get constant potential. He could hardly imagine there could be any machine which would not lose its field on open circuit with so little shunt as that.—*Q.* Do you find anything as to the mode of winding disclosed in Brush's specification that is not already disclosed in Varley?—*A.* There was nothing disclosed in Brush as to series shunt-winding that was not disclosed in Varley's specification. Varley said he covered the magnets with two wires, and that the one of larger resistance was always closed, and the one of less resistance was used for the electric light. If the one of less resistance were not in series with the electric lamp there would be no particular reason for denoting that as an electric light circuit; neither of them would be an electric light circuit. Varley went on to say that when the electric light circuit was open from any cause the electricity developed passed through the circuit of greater resistance only, and maintained the magnetism of the magnets. That showed that when the electric light circuit was not open electricity did not pass only through that circuit of greater resistance but passed through both the circuits; therefore, the circuit of low resistance must have been in series with the arc light. *Q.* It has been suggested that the method of winding there described might be a method by which there should be separate excitation from different parts of the armature; do you think that is consistent with what you find in the rest of the specification? *A.* It is inconsistent with the whole of the description of the machine in the specification. That description showed that the bobbins of the armature were all connected together in series, and that was inconsistent with a separate part of the armature being used for excitation, and that was also clearly shown in one of the figures. Besides the dynamo, Varley described a sort of semi-incandescent lamp, which he called an arc lamp. Series shunt-winding was very much a desideratum for that lamp as described. [Shown Varley's machine, No. 29 of productions.] Apart from other things, the thick wire was too thick to be connected with a second shunt. *Q.* Can you tell, as matter of fact, from that machine, that it was not used for separate excitation?—*A.* Yes; there is nothing to take the portion of the current off, and all the bobbins are accounted for. The present commutator was exclusive of the idea of working by separate excitation. If he were told as a fact that when that machine was used and when the electric light was burning the magnetism of the machine was more

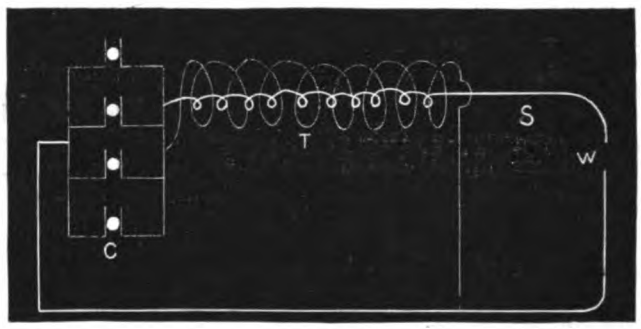

FIG. 1.

The above diagram is taken from the rough sketch made by Mr. Varley in his private note-book. See *The Electrician*, Nov. 30, p. 114.

Digitized by Google

largely developed than when the lamp was not burning, that would show clearly that the electric arc was in series with the wire round the field-magnets. If he were also told that when they worked the machine with the lamp on they found that the machine became bound by the magnets pressing upon the armature, that would show the same still more conclusively. He had seen Varley's sketch, which clearly showed series shunt winding. [Fig. 1 is a facsimile of the sketch referred to.]

Cross-examined: *Q.* Between Varley's wearing segments and Brush's wearing segments is there not this difference, that Varley's are fastened on to the other segments by pins, and in Brush's by a peculiarly-shaped screw with a long head?—*A.* The pins in Varley's are screwed at the end, and the only difference is that Brush's have a longer cylindrical head. The rivets in Varley's were a different arrangement fom the screws in Brush when they were put in, but there was not much difference when taken out. He believed that in the Crompton case they submitted to an injunction, and paid £2,000. He had never heard of a series shunt-wound machine before Brush's. *Q.* Is it not the case that Brush's machines show a very much larger resistance in the shunt than in the series winding?—*A.* I cannot say that the drawings show much about resistance at all; they are simply drawings to show the place of the wires. *Q.* Would not machines made with wires of those proportional thicknesses have a tendency to produce constant potential?—*A.* Compared with a series machine he thought a machine made according to the proportion he found existing in these figures would tend towards constant potential; compared with a shunt machine he thought it would not. He would expect to find in a specification instructions by which a skilled workman could find his proportions.—*Q.* Would not a skilled electrical workman find out for himself according to the requirements of the machine he was told to make, and the proportion of the wire to put on?—*A.* It took Brush five years to find out constant potential in this specification, and I must say I have not found it yet. He was not aware that Sir W. Siemens took out a patent for a small shunt-winding machine in 1879; if he did, he must have been very lax, because it had been already described. In Varley's specification if they wound shunt and series so that the resistance would be nearly the same, he thought the machine would heat so much as to destroy the insulation. He had measured the resistances of the armature and field-magnet coils of Varley's machine, and he thought the figures would be about 9 ohms for the armature, about 2 ohms for the large wire coil, and about 10 ohms for the small, and the diameters were, he thought, ·124in. and ·042in.

Re-examined: Constant-potential or compound-wound machines were brought into use by Crompton in the end of 1882 or beginning of 1883. Other makers took them up in 1883 or 1884. The descriptions of the Brush machine in those days gave other modes of securing constant potential, such as automatic regulators worked by little belts.

Re cross-examined: *Q.* Were these automatic regulators brought into use by the British officials of the Anglo-American Brush Company intended to apply to machines in order to get a constant current as contrasted with a constant potential?—*A.* No; the things I think of were for constant potential for incandescent lamps. Crompton paid royalty to the Brush Company for every one of those compound-wound engines he made.

JAMES ALFRED EWING, Professor of Engineering in University College, Dundee, gave evidence as to the commutators described in the two specifications being of a similar character to that given by previous witnesses. With regard to Brush's seventh claim, he found no hint in the specification from beginning to end of his having thought of the desirability of trying to obtain a machine which would work with constant potential. At the date of Brush's patent constant potential was not a special desideratum. Varley's specification clearly described a series-shunt winding. There was also disclosed in Varley's specifications a certain form of lamp for producing an arc light. For that particular lamp series-shunt winding would be a distinct advantage.

Cross-examined: He did not think that an approach to constant electric potential was of any advantage to electro-plating, not even when the articles to be electro-plated were in parallel in the bath. He should prefer a plain shunt machine to a series shunt-wound machine for electro-plating. He did not hear of series-shunt winding till long after Brush had published his patent in this country. He had seen several Brush machines before compound winding for self-regulation became common, and he never saw one of them which was a series shunt-wound machine. The Brush machines which he saw were plain series machines.

Re-examined: If he made a machine according to Brush's specification, and set it to work, the chances were one million to one that he should not get anything like constant potential.

JOHN WALKER, foreman model maker in the Museum of Science and Art, Edinburgh, produced a model which he had made from Varley's specification, at the request of Mr. Brown. He told witness nothing about compound winding.

ANDREW B. BROWN, one of the pursuers, said the description given of his instructions to the four witnesses who had made models for him was perfectly correct. He knew about the action at the instance of the Brush Company against the Orient Steam Navigation Company regarding a machine made by witness. He understood that judgment went against the Orient Company, but his firm declined to have anything to do with the action, and no one connected with the firm had agreed to keep the Orient Company free of expense in that case.

This concluded the case for the pursuers, and the Court adjourned till next day.

FRIDAY.

DEFENDERS' PROOF.

The case for the defenders was opened to-day before Lord Trayner, the first witness called being

SILVANUS P. THOMPSON, B.A., D.Sc., who deposed that he was Principal of the City and Guilds of London Technical College and Professor of Physics in that College. In 1879 the shunt arrangement was not one likely to be known to an ordinary electrical workman, and no machines to his knowledge had been constructed in 1879, or were in practical use. At the date of Haddan's specification, in 1878, the machines which were well known belonged to four classes—permanent-magnet machines, machines excited from a separate source, machines excited in series, and machines excited by a separate but self-contained circuit. That equally applied to the year 1876. [Shown a diagram.] That represented a series-shunt arrangement as described by Haddan. The name witness used for it was the "long-shunt" arrangement. [Shown another diagram.] That represented another series-shunt arrangement described by Haddan, known as the "short-shunt." These were mere modifications one of the other. The effect of the series-shunt arrangement described by Haddan as contrasted with the mere shunt arrangement was this, that when you draw larger current from the machine, the potential instead of rising, as it would do in a mere series machine, will not rise so much; or, in some cases it might remain perfectly steady, or in some cases it might even fall. Comparing it with the shunt arrangement, whereas with the mere shunt arrangement when you draw more current from the machine the potential would fall, in the series-shunt arrangement the potential would either in the one case not fall so much, or in the other case remain firm, or in the other case might even rise. In the series-shunt machine the two opposite tendencies which he had mentioned as affecting that machine tended to counteract one another in every case, and by tending to counteract one another they tended to keep the potential constant. *Q.* In whatever proportion the diameters of the wires are, and in whatever proportions the number of coils of the two wires are, is the joint effect of two wires that each wire to a greater or less extent supplements the other?—*A.* Yes. *Q.* And each wire to a greater or less extent prevents the disadvantages of the other from being felt?—*A.* Undoubtedly. *Q.* In short, do the two compensate one another?—*A.* They do. They did not always accurately compensate, but they tended to compensate one another. That tendency to compensate was a most valuable step in advance. *Q.* Had anything of the kind, to your knowledge, been disclosed or suggested prior to Haddan's patent?—*A.* Not by means of double-winding. There had been various attempts to regulate the strength of the electric current by devices that required moving by the hand—the introduction of additional resistance and the like; but automatic arrangements of this kind depending upon the compensation between the two wires, one in series and one in shunt, was at that date entirely new. Haddan's specification described the series-shunt arrangement accurately and with remarkable detail. The drawings attached to the specification were such as would unquestionably enable any workman who followed them to make a machine which would have the advantages he had described. Referring to the letterpress of Haddan's description, he had no recollection of any passage in which he professed that his machine should produce constant potential. *Q.* Although Haddan does not profess that his machine shall produce constant potential, are you able to say whether, if a machine was constructed according to the description and the drawings, it would, or would not, in fact tend to produce constant potential?—*A.* It does as a matter of fact; I have tried it. The degree of approximation to constant potential depends upon several circumstances, including the speed at which the machine is driven, the proprotions between the coils, their resistance, and the number of turns of wire in the separate windings. He had tried a machine according to Brush's drawings and from Brush's specification, and he found that when used it did approximate in its potential and constancy. The speed at which that machine was driven was 1,250 revolutions per minute, the ordinary speed, and the current that was drawn from it varied from nothing up to 211 amperes. The potential remained very nearly constant. It increased slightly at first, and it fell slightly afterwards. When there was no current drawn from the machine the potential at the terminals was 3·54 volts; when 100 amperes were being drawn it had risen to 3·68 volts; at 125 amperes it had fallen back to the original 3·54 volts; when 150 amperes were drawn it fell to 3·45 volts; and it remained at that with the highest current drawn—211 amperes. He examined the machine to see whether it was in terms of Brush's specification. It was obviously an old machine. He examined a similar machine in February of this year also at Brush's works, and also a machine which he found to correspond with Brush's specification, and the performance of which was almost the same. Series-shunt machines were now very extensively used. They had not superseded all other dynamo machines. *Q.* Has subsequent invention or experience added anything to what Brush mentions in his specification, and if so, what?—*A.* Experience has added this: that where a type of machine has been manufactured, and its qualities are known, you can now calculate beforehand the proper amount, thickness, and so forth, of the two windings to be afterwards wound upon that machine. *Q.* As to the proportions, would it be possible in the specification of a patent to give proportions which would be of material aid to a workman in constructing such a machine?—*A.* I am afraid such instructions would mislead the workman, because he would think there was some fixed proportion. It would be far better if they had given him instructions how to make experiments for the proportions for each machine or each type of machine. *Q.* If Brush had given directions for the proportions in which the coils were to be laid on, would he have given directions that would have been materially valuable to a skilled workman for the purpose he had in view?—*A.* They would have been valuable for a particular type, but would have been misleading if they had been interpreted for all types. *Q.* In your opinion, could Brush have given better directions than he has done?—*A.* At that date I think not because he was ahead of all of us who were working at the theory of the subject. Brush's description left witness in no doubt whatever that he supplied his coils by a bifurcated current. That was absolutely so, because he said "it divides itself between the external circuit and the teaser inversely as their respective resistances." It could not have been more definitely described to an electrician. The armature generated current, which was

Digitized by Google

delivered through the commutator to the springs or brushes, and after that it went to a certain place where it bifurcated. For the purpose of electro-plating, Brush's series-shunt machine was a great improvement upon magneto machines and series machines, and possibly machines separately excited from a separate source, so far as it enabled the machine to adjust its operation to the work in the bath. Another advantage was that it was less liable to reverse if the speed dropped than the series machine. With regard to Varley's specification of 1876 he had been referred to the passage on page 8, lines 38 to 49, where Haddan's invention was said to have been anticipated. That passage was not made the subject of any claim. A machine might be made under claim 1; that had nothing whatever to do with that passage. I do not understand the claim to be for the machine at all; it is a principle—cutting out some bobbins. He had considered the description with the specification of the arrangements in the course of which the passage relied on was introduced. There were several electrical absurdities in the course of the description. There is a thing which was electrically absurd on page 6, line 46:—"The force consumed in giving motion to the machine is being converted into magnetism and electricity at the same time, and the magnetism produced is less proportionately as electricity is developed." That was an erroneous notion altogether. The alteration in the magnetism and the fluctuations of the electricity went on simultaneously, and you wish, as a matter of fact, to have the greatest alterations in the one in order to get the greatest development in the other. What was then mentioned as a fault in the existing machines was absolutely the way in which the machines really worked. Varley went on: "My improvement consists in separating the development of electrical and magnetic forces to a considerable extent"—that was a mere consequence of his erroneous notion—"obtaining thereby greatly increased magnetic potential in the bobbins, which at a later stage becomes converted into electricity of a corresponding high potential." That was nonsense, because it was the consequence of an erroneous theory, and was equally an electrical absurdity. He had not met with any electrical absurdities in Brush's specification. Taking the passage in Varley's specification, on p. 8, line 38: "Part of the electricity developed by the machine is diverted to maintain the magnetism of the soft iron magnets, and the remaining portion is used to produce electric light," and stopping there that passage was not consistent with a series-shunt arrangement. It was consistent with the use of a shunt, because in shunts, as in a separate-circuit arrangement, part of the electricity developed by the machine was diverted to maintain the magnetism of the magnets, but it was inconsistent with there being a series winding, because the remaining portion does not go round the magnets and produce the electric light. The essential characteristics of series-shunt winding were that the whole of the electricity produced shall travel round the magnets, part through one coil, part through the other coil. These characteristics were negatived by the last part of the sentence he had read. He went on to say, "There were several well-known ways of doing this," and by this witness understood him to mean diverting a part of the electricity developed by the machine to the magnets. The ways of doing this that were well known in 1879 were three varieties of excitation by a separate self-contained circuit. There was the method devised by Wilde, there was another device by Ruhmkorff, and the third method was described by Ladd. In witness's opinion any electrical workman who was told to divide up the electricity of the machines at that date would instantly have thought of Wilde's, because Wilde's machines were, perhaps, the best known at that time. The shunt arrangement would not have been known to the workman. In Wilde's a few of the coils of the armature were separately connected up to a circuit which went round the field-magnets so as to form a separate circuit internal to the machine, the magnetism being developed within the machine, but by a separate part of the machine. Varley in his 1867 patent had described a somewhat similar mode, but with two windings on the field-magnets, as well as on the armature. The two currents came from separate sources. There was no bifurcation. *Q.* In short, the principle of bifurcation was not in 1876 a thing known to any electrical workman?—*A.* I do not think the electrical workman would ever have heard of it. Varley in his specification proceeded:—"The method I prefer is to wrap the soft iron magnets with two insulated wires, one having larger resistance than the other. The circuit of larger resistance was always closed, and the circuit of less resistance was used for the electric light." That differed from Varley's 1867 machine only in one respect. There were two circuits side by side distinct, each going to its own winding; but now the two windings being alike, one had a higher resistance than the other. There was no suggestion of any distinction as to the source of the electricity; it appeared to be exactly as before. There was nothing so far inconsistent with the Wilde arrangement, or the Ladd arrangement, or the Ruhmkorff arrangement, but there was something supplementary to it. The next paragraph in the specification was—"When the electric light is being produced the greater portion of the electricity passes through the circuit of less resistance, which I term the electric-light circuit, in sustaining the magnetism of the magnets and producing the light. When the electric-light circuit is opened from any cause, the electricity developed passes through the circuit of greater resistance only, and maintains the magnetism of the magnets." In witness's opinion, taking the state of electrical knowledge in 1876, that passage would not have conveyed to any ordinary electrical workman the suggestion of series-shunt winding described by Brush, taking that passage as a whole. He thought it would have led him to suppose that these two windings were to be supplied from two separate groups, or portions of groups, of coils on the armature, and that they worked alternately, that the current went from one armature through one winding one way, and that the other current started from the other armature through the other circuit, as in the 1867 machine. The whole description was consistent with the circuit of greater resistance being a circuit complete in itself and separate from the electric-light circuit. It was quite consistent with the division of the electricity being effected in what he had stated was the then usual manner. There was no direction or suggestion whatever in that passage that the division was to be effected by the bifurcation of the original common current. Taking the specification as a whole, or confining himself to any part of it, his opinion was that it did not disclose the series-shunt machine as described by Brush. It was not fitted to suggest to a skilled workman having the knowledge of the period such an arrangement as that of Haddan. In Haddan's arrangement the shunt actually formed a closed circuit within the machine. It was so described and so shown on the drawings. Varley's circuit of greater resistance was taken outside the machine. So taken out of the machine it was taken to work the motor of the lamp. Being so employed, it would not serve the same purpose as Haddan's circuit of greater resistance closed within the machine. It served a different function. Brush warned you specially against the waste of current if the shunt-circuit was not of much higher resistance. Witness did not know any passage in Varley to warn the workman against making the coil of high resistance of nearly equal resistance to the other. If it were merely made higher and not greatly higher the machine would destroy itself. Cromwell Varley's communication to the Royal Society, where there was a reference to a secondary wire or a copper cylinder, did not suggest to him any resemblance to the series-shunt arrangement. He did not see that it had very much bearing upon his evidence as to the passage relied upon on page 8, because in the first place it had nothing to do with the mixed series-shunt winding; and, secondly, this secondary wire or copper cylinder which was to be placed on his magnet acted in a wholly different way. It was not furnished with any of the electricity coming from any armature coil of any kind. It merely acted as a damper. It maintained magnetism in this sense, that it damped fluctuations of the magnetism, and it could do nothing more. He had examined Varley's machine made by Siebe and Gorman. There was nothing in it to show how it was coupled up when it was used. There were an unnecessary number of terminal screws to receive the ends of the wires, and that would indicate beyond all question that it was intended to try coupling up that machine in various ways. *Q.* Could the machine, as you see it, be used as a shunt and series machine, or double shunt or double series?—*A.* It could be used in any of these three ways or more. It could be used as a separately-excited machine; it could be used in every other way he had described except permanent magnets. He had read the passage in Haddan's specification which related to the commutators, and he had also examined the passage in the final specification which referred to the commutators and the claims for the commutators. There was nothing in the commutator claims which appeared to him to go beyond the fair carrying out of the arrangements described in the provisional specification. They referred mainly to making the commutators of easier construction and of more ready repair after wear. He had examined the commutator on Varley's machine; but he could not see that it anticipated Haddan's commutator. The wearing segments did not seem to be detachably fastened, so as to allow of repair in the same way.

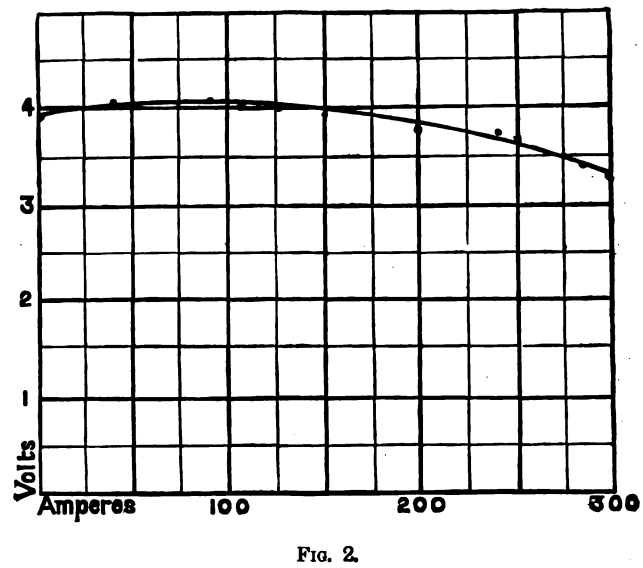

FIG. 2.

Cross-examined by Mr. MURRAY: Siemens' communication in 1880 investigated the utility of shunt winding, treating it as an old thing. Clark's specification was a disclosure of pure shunt, and at a date previous to Brush. It gave a hint that pure shunt would be very useful in electro-metallurgy. It was the case that in Brush's patent, as originally framed, he had a claim which claimed pure shunt, and one of the methods he disclosed in the description of his machine was pure shunt. That was afterwards disclaimed. He imagined that Varley would know of the existence of shunt at the date of his patent. [Shown No. 40 of productions.] So far as that drawing went, it indicated a series-shunt arrangement. *Q.* Do you take it that the object of Brush's invention was to give a constant potential?—*A.* He never says so. *Q.* On the other hand, he does say that his object is to secure a permanent field?—*A.* One of his objects. *Q.* And if he has another he does not say what it is?—*A.* Yes, he indicates it distinctly; he says it was to enable his machine to do either a large or a small amount of work. He should have expected much more specific instructions than were given in Brush's specification if the patent had been one for constant potential. In witness's view there was still

Digitized by Google

potential matter left for the getting of constant potential after Brush had made his discovery of compound winding; and further application of compound winding to attain constant potential was patentable after Brush's patent. Crompton, among others, took out patents. Being shown *The Electrician* of date Friday, 2nd Oct., 1885, with supplement called the *Exhibition Record*, he said there was a diagram there of a Brush electro-plating dynamo (Fig. 2). That diagram showed the working of one of the old Brush machines as regarded constancy of potential. *Q.* Is it very bad? *A.* It is a great deal better than anything before that time; it is nothing like what constant potential is now. It tends to it, but it is not good enough. There was nearly 20 per cent. of variation upon it. It was a matter of opinion whether pure shunt was better for the purpose of electro-plating than series shunt. With series shunt it was possible that the polarity of the magnets might become reversed, but not probable; with pure shunt it was impossible. In 1878 he did not know of any case where the incandescent light was a proved success. He believed the difficulty was to discover a perfectly suitable lamp. That came about by degrees in 1878 and 1879, and it was introduced commercially in 1881. As soon as it did come in, that made it most desirable to have constant potential. As a matter of fact, a great many methods were tried for ensuring constant potential. The Brush Company in England proposed several kinds of regulators for the regulation of the dynamos, so as to ensure constant potential. Allan's patent automatic regulator was about 1883. Most of these devices were prior to the discovery of those conditions of proportionate resistance, and so on, which they now knew, and which ensured constant potential in a series-shunt machine. It would be quite useless to have an extraneous device when you could secure it in the machine itself by simply wrapping the wires in the proper way.

This concluded the evidence for the day, and further hearing of the proof was adjourned till Wednesday.

(TELEGRAM FROM OUR CORRESPONDENT.)

EDINBURGH, THURSDAY EVENING.

Evidence for defenders concluded to-day. The cross-examination of Prof. Pirie was completed; and after hearing the evidence of Mr. Alfred Hicks, Sir. Wm. Thompson, Mr. W. H. Preece, and Mr. P. Sellon, the Court rose. The hearing of the case will be resumed in January, after the evidence of Mr. Brush, taken on commission, has been received.

[A full report of the proceedings on Wednesday and Thursday will appear in our next issue.]

Edison and Swan Electric Light Company v. Holland and Others.

THE CASE ON APPEAL.

The hearing of the plaintiffs' appeal against the judgment of Mr. Justice Kay, finding that the patent of Edison's incandescent lamp was not protected because the method of working was insufficiently set forth in the specification, was commenced on Saturday in the Court of Appeal, before Lords Justices Cotton, Lindley, and Bowen. Sir William Grove, the distinguished scientist and inventor, and late a Justice of the High Court, also occupied a seat on the Bench. The counsel for the plaintiffs were the Attorney-General (Sir Richard Webster), Mr. Aston, Q.C., Mr. Moulton, Q.C., and Mr. Bremner; the defendants were represented by Sir Horace Davey, Q.C., Mr. Finlay, Q.C., and Mr. J. C. Graham.

The ATTORNEY-GENERAL said he appeared on behalf of the appellants in respect of the infringement of two patents vested in the Swan United Electric Light Company, and known as the Edison patent and the Cheesbrough patent. Both patents were before the Court in the case of "Edison v. Woodhouse and Rawson." The Edison patent related to the mode of construction of an incandescent lamp; the Cheesbrough patent related to the method of preparing in a better way the conductor to be used in incandescent electric lighting—that was to say, the carbon. Mr. Justice Kay found for the plaintiffs in respect of the Cheesbrough patent, relating to the improved method of conducting the material of the conductor, and he found on a number of issues for the plaintiffs in the Edison patent; but he found one matter against them, namely, the deficiency in the specification as to the method of working. There was no appeal against Mr. Justice Kay's decision with respect to the Cheesbrough patent; the judgment for the plaintiff, the injunction and the consequences stood as in Mr. Justice Kay's judgment. This appeal was by the plaintiffs against that part of the judgment of Mr. Justice Kay which found for the defendants on the ground that objection could be taken to the Edison patent. In the Court below the case lasted for twenty-three days, but on appeal he thought it need not last a quarter of that time; but it was essential in the first place to put before their lordships a general outline of the case. Amongst the issues which were found for the plaintiffs was that Mr. Edison was the true and first inventor, the combination which he described was new, and that the defendants had infringed; but at this late day in the life of this patent the learned judge found that there was not sufficient information given in the specification to enable a competent workman to construct this combination. There was one other point of considerable importance which was to a certain extent interwoven with the one to which he had just referred. Mr. Justice Kay applied to this specification a test which, so far as his reading went, was absolutely new, and, as he should submit, contrary to the principle of the patent law; that was the test of commercial utility as distinguished from utility generally. He would in the course of the case have occasion to call atention to legal authority to show that the test which Mr. Justice Kay applied in construing this specification was incorrect in law, and not in accordance with decisions so far as that question ever had been dealt with. Indicating the line of argument he proposed to follow, the Attorney-General said he proposed to state as fairly as he could what was the existing state of knowledge at the date of the patent, as he stated it before Mr. Justice Butt in the case of "Woodhouse and Rawson," and before the Court of Appeal in that case, and before Mr. Justice Kay in the present case. Having done that he proposed to call attention to the specification of Mr. Edison, and to see what was the invention on the face of the specification. He then proposed to take the judgment of Mr. Justice Kay, and to show (with very great submission to his opinion) the errors into which the plaintiffs alleged that he had fallen, and then, with the assistance of his learned friends, to bring before their lordships' attention so much of the evidence as had a direct bearing on the issue raised by Mr. Justice Kay's judgment. One observation suggested itself on the threshold of the attack which he was about to make upon the finding in favour of the defendants. The experiments upon which the sufficiency of this specification was attacked were substantially —and he might say almost without exception—experiments made after the trial of the action had been actually commenced. He would be able to demonstrate that the defence as to the insufficiency of the specification was a complete afterthought, the experiments upon which the attack was made having been made after the principal witness for the plaintiffs had been examined. The plaintiffs called rebutting evidence, and in consequence of that rebutting evidence, which was of a most remarkable character, Mr. Justice Kay said he would have the experiments repeated before an independent referee, and Prof. Stokes, of the University of Cambridge, was chosen as referee, and made a report to the Court, stating that, without exception, on every-one of the matters of attack which was brought against Mr. Edison's specification the witnesses for the defence were absolutely and entirely wrong. He would show to their lordships that the attacks which were made by expert witnesses to endeavour to break this patent down after a life of ten years on the ground of the insufficiency of the specification were, according to Prof. Stokes's report without foundation. Nay, more, when he came to deal with the judgment of Mr. Justice Kay, he thought he would be able to show their lordships that there was, possibly owing to the length of the case, and possibly owing to the cause which he would rather not refer to at present, but which he might have to say a word or two about later on, a forgetfulness in the mind of Mr. Justice Kay as to certain most remarkable things that had been proved. The Attorney-General then proceeded to deal with the state of knowledge at the date of Edison's patent, which was dated 10th November, 1879. In this case they had nothing to do with the power which produced electricity. They had nothing to do with the sources from which electricity was derived or supplied. [The leading features of the incandescent lamp were then described at some length]. The earliest incandescent lamps were made in the year 1845. From 1845 down to 1879 these attempts went on, the experiments being revived from time to time, without any success at all, or rather without any success which led to the development of incandescent lighting. In the specification of 1879 Mr. Edison no doubt did disclose things which formed a part of Mr. Swan's patent. Mr. Lane-Fox had previously discovered that high-resistance lamps were more likely to succeed than lamps of low-resistance, and he devised a means of mixing up non-conducting material with conducting material, as for instance, asbestos with carbon, but the idea of a carbon filament wholly escaped him. So far as prior knowledge was concerned this was about the condition of makers; it was known long before 1879 that you could raise to incandescence conductors of various kinds; known long before 1879 that carbon was a suitable conductor; known that high-resistance lamps were likely to be of more advantage for the purpose of incandescent lighting as compared with lamps of low-resistance; known that a vacuum was the proper condition for the success of these lamps; but it had occurred to no one that a simple carbon in the shape of a filament was sufficiently strong to fulfil the conditions. Therefore, when Mr. Edison grasped the idea and enunciated it in a form capable of being carried into practical effect, a step—a marvellous step—was made in connection with the invention. For forty years people were trying to overcome the difficulties of electric lighting almost in the same way, and Mr. Lane-Fox, one of the most remarkable names connected with the history of electric lighting, and one of its most remarkable prophets, tried his hardest to perfect an incandescent lamp by strengthening the bridge by the use of non-conducting materials, because he thought conducting materials had two effects—those that were of sufficiently high resistance were too weak to stand the strain; those that were strong enough were bad conductors. Then there was the discovery of Mr. Justice Grove with reference to platinum wires; but though platinum was a good conductor the current required was so large that the glass was cracked by the heat used to raise the platinum wire to incandescence. A notable name that would figure in the case was that of Mr. Joseph Wilson Swan, to whose indomitable perseverance the present perfection of the lamp was due. Having worked at the matter for fifteen years, in the autumn of 1878 Mr. Swan got the nearest approach that was ever made to the Edison lamp or the subsequent Swan lamp prior to the publication of Edison's specification. [A Swan lamp of 1878 was here handed up to the Court.] He should state, to be accurate, that the lamp was made by Stearn, but it had always been called Swan's lamp, and was really the outcome of mutual experiments made by Swan and Stearn. It consisted of a globe of glass, with platinum leading wires, and of a pencil or stick of carbon, the history of which was not known when the case of "Edison v. Woodhouse and Rawson" was originally before Mr. Justice Butt, but had since, fortunately, been fully ascertained from Mr. Swan himself. That lamp was made in December, 1878, but although Mr. Swan and Mr. Stearn had worked the matter out theoretically and, to a certain extent, practically, the result they arrived at positively led people astray, and it led even Swan and Stearn themselves in the wrong direction. The most powerful argument that could be adduced in favour of Mr. Edison was the evidence of the men who were supposed at that particular time to have anticipated Mr. Edison's invention, not publicly, but in their own minds, and it was now fully recognised and ad-

Digitized by Google

mitted that Edison had anticipated Swan in this discovery. This was clear upon correspondence which had taken place at the time, which had been accidentally preserved, and was now in evidence, and the fact would be plain beyond all doubt. Although the experiments of Swan and Stearn had been a great success, and although it was admitted they had come close to Edison's invention, yet it led Swan and Stearn completely wrong, so little did anybody think that the solution lay in the direction of a filament of carbon; so little did they know its flexibility, its resiliency, and other characteristics. After the supposed anticipation of Edison, through the year 1879 Stearn and Swan were experimenting with a view to a patent, and the defendants attempted to set up the case that they produced a lamp with a carbonised thread which was the same thing as Edison described. In the summer of that year, said the defendants, Mr. Swan showed to a number of people carbonised thread lamps, which were working to the number of hundreds at Newcastle; but Mr. Justice Kay had found for the plaintiffs that, even if such evidence were true, any such attempts were wholly experimental. As a matter of fact, it could be shown, if necessary, that these witnesses were misstating the time, and that no thread lamp was ever made by Swan until January, 1880, a date fixed clearly by the fact of a fire at Mr. Swan's works, by which everything was burned down, so that he had to start *de novo*. But besides this, there was the statement of Messrs. Swan and Stearn themselves, that they never did make a thread lamp until after the publication of Edison's specification, or ever even tried to carbonise thread. The defendant relied somewhat upon an article in *Electrotechnische Rundschau*, but this was admittedly written with a view to minimising the value in Germany of Edison's invention. Of course, if the defendant could prove publication by Swan prior to 1879, he must absolutely succeed, but both Swan and Stearn stated that the thread lamp of Swan was not made until the year 1880. That point was of the gravest importance. As a matter of fact, nothing nearer to Edison's lamp than Swan's lamp of 1878 was ever published. Swan and Stearn both failed to realise that they might make the carbon very much smaller than it was in the lamp of 1878; they still thought they must have a strong and relatively massive carbon conductor, and they were working in the direction of strengthening and thickening the carbon conductor instead of thinning it and making it filamentary. The resistance of a lamp varied in proportion of the length to the width of the cross-section; with a given cross-section the longer the conductor the higher the resistance, or, in other words, it required more electricity to raise it to incandescence. The resistance, therefore, depended not only on the width of the cross-section, but upon the length of the conductor used. The Attorney-General then called attention to a number of lamps made by Messrs. Swan and Stearn, as to which he observed that they formed an interesting museum record of the steps of invention. But in all these lamps they were trying different forms of thicker and stiffer carbons. What was the consequence? They immediately got a much higher current of electricity and more heat in the lamp. In all those cases coils of platinum wire in the bottom of the lamps might be noticed, being placed there for the purpose of getting rid of the heat. The carbons were of different forms, one being like a horseshoe, but in one and all some method was adopted of getting rid of the heat by placing a good deal of metal in the lower part of the lamp, with a view that the necessarily high current should be diffused by radiation or conduction through the platinum and the glass, and so to the outer air, so getting over the difficulty of the cracking the glass. It never entered into the minds of Swan and Stearn, any more than it did into the minds of the distinguished men who preceded them, that they should experiment in the direction of relying upon carbon in a filamentary shape, that the problem was to be solved, and solved most effectively, by the utilisation of a filament of carbon, without any additional material to strengthen it, but that it would have sufficient resiliency, sufficient stability, and strength to do the work. It was no exaggeration to say that every single effective incandescent lamp, of which there had been hundreds since the date of Mr. Edison's specification, might be in terms described in the words of Edison's specification, and, indeed, Stearn wrote to Swan before the specification came over, "If Edison means carbon, we are anticipated." That statement was in black and white, and was of itself quite sufficient to dispose of the idea that Swan had already made the lamp in 1879. Coming to the specification of 10th November, 1879, Sir Richard Webster said he proposed to read it with two objects, firstly, to describe what Edison described as his invention, and, secondly, to bring prominently before their lordships' minds the point upon which Mr. Justice Kay had thought there was not sufficient description to enable the work to be done, that being the only issue which had been found against the plaintiffs.

LORD JUSTICE LINDLEY: I suppose in this appeal they rely upon anticipation, or have they given that up?

The ATTORNEY-GENERAL said that his learned friends had given nothing up, and he had never known them to give up anything that was arguable, or even after it had ceased to be arguable. Beyond the fact that Edison did not know accurately everything that had been done in England, the specification would be found to be not an incorrect summary of the state of knowledge at the time. Edison was not quite aware of what had been done in some respects in England. One objection taken against the specification was that the words "properly carbonised" did not convey sufficient information to enable persons to carbonise, but there was not the slightest foundation for saying that the term was not perfectly understood and known by persons having to do with the carbonisation of articles. The description of the filaments as "fibrous vegetable substances coiled" as a description of the most successful electric lamps was applicable to this day, and except in so far as they differed in construction they answered exactly to the description which Edison had enunciated in his specification. Then Edison went on to say, "I have discovered that carbon filaments may be made by a combination of tar and lampblack, the latter being previously ignited in a closed crucible for several hours, afterwards moistened and kneaded until it assumes the consistency of thick putty." That was stated by the defendants not to convey sufficient information to enable a person to do it. The process also was said to be impossible and absurd, and so bad was the specification said to be by some of the defendants' witnesses that they had never tried it. Others said they had tried it, and had failed to do it. But he could show that it was done by boys and girls in the most ordinary and common way, and without the slightest attempt at skill or scientific construction. Everything in the specification had been shown to produce a useful lamp. Then it was said that the making of filaments in this way could only be done by a trick, as the ignition would burn the whole thing up, but it was proved to be possible by the referee appointed by Mr. Justice Kay. But when Mr. Justice Kay came to deal with the matter, he disregarded everything that the referee had said with regard to its feasibility or practicability. The specification also said that small pieces of this substance might be rolled out to the size of $\frac{7}{1000}$in. One witness said it was impossible to get a size less than half a millimetre, and that it could not be carbonised, as it would all be burnt up in ash, but it was proved by plaintiffs' witnesses that hundreds of filaments as thin and thinner than this were made by a boy, and carbonised afterwards without difficulty. Prof. Dewar also did it; but this was disregarded by Mr. Justice Kay when he came to deal with the matter. He would ask their lordships to watch most narrowly the point of attack made for the first time in this case by the evidence of people who had never tried the process until after the case began, and until after the witnesses for the plaintiffs had given their evidence, and to contrast it with what had actually been done by persons who had nothing but the instructions of the specification to go on. It was also alleged for the defendant that this carbon wire could not be rolled out at all. Then said Mr. Edison, "The same may be coated with a non-conducting non-carbonisable substance and wound on a bobbin"—the object of the coating and winding upon some such material as a pipe-stem being to keep the coils separate—"and carbonised in a close chamber by subjecting it to a high heat;" the material, after carbonising, retaining its form. Filaments in accordance with the various processes were actually made in court or in a chamber adjoining, under the very eyes of the learned judge. When he came to deal with the evidence of the defendants' witnesses, he would say, unhesitatingly, that they failed because they did not take pains to succeed. They were found out by Prof. Stokes. They tried to carbonise in an unsuitable crucible not impervious to water, and consequently not impervious to air. It all appeared upon the report of Prof. Stokes. With regard to carbonisation, the thing was said to be absurd and impossible, but Prof. Stokes never found a failure, and when the defendants' witnesses failed the cause of their failure was pointed out to them at once.

Proceeding with the specification, the Attorney-General pointed out that a modification of the carbon by an admixture of powdered camphor or oxide of zinc was provided for, but, according to the defendants, they were said to be things which could not be used, but every one of the lamps made in accordance with Edison's specification fulfilled the conditions of an incandescent lamp subject to one condition, viz., the length of time during which the lamps were burnt. He challenged his learned friends who represented the defendants, when they came to deal with Prof. Stokes's report concerning the process for the formation of the thread or fibre, to show that it required anything more than ordinary workmanlike knowledge.

Proceeding to speak of the grounds on which it was said that it was impossible to carbonise these filaments properly, the Attorney-General said there were several methods of carbonising known, such as packing the article to be carbonised with sand or powdered charcoal, but according to Mr. Edison's process they were not surrounded with anything at all, but simply placed in a closed chamber; but the defendants' witnesses asserted in the most recklessly positive manner, and upon one experiment only, that such a method of carbonisation was impossible. To carbonise these filaments with sand was, they said, ridiculous, and could not possibly succeed; and people did not know that they ought to carbonise with powdered charcoal. In reply to that it was shown by contemporaneous literature that carbonising with powdered charcoal was perfectly well known, and the admissions of the defendants' witnesses practically went to the same extent.

LORD JUSTICE BOWEN: What is the object of surrounding with sand and powdered charcoal?

The ATTORNEY-GENERAL said it was to prevent the oxygen which might be evolved doing combustion work in the chamber. Oxygen might get in from the outside if the chamber were not properly closed, or might be evolved from the material itself; it was to prevent the oxygen burning up the thing which was to be carbonised. Prof. Stokes did not find a sign of failure, both sand and powdered charcoal being used and also a material called kaoline. Yet, in the face of all this, Mr. Justice Kay said the patent was bad because there were not sufficient instructions with regard to carbonisation. It was admitted by the defendants that carbonisation by powdered charcoal was known; but it was contended that there was not in the specification sufficient indication to the workman that he ought to use it. He did not hesitate to say that the attacks made upon the specification were unworthy attacks, and made by people who had not attempted to carry it out, as he would demonstrate upon the evidence itself. How was it that gentlemen like Prof. Crookes, Prof. Silvanus Thompson, and others failed? Prof. Stokes discovered that it was because they used a crucible which would admit the air. It was really almost impossible to believe that scientific gentlemen wishing to inform the Court should have taken so little pains as these gentlemen did. The learned council then said he would proceed to deal with the enunciations of the objections to this patent put forward by the witness, and was engaged in dealing with the evidence of Prof. Crookes when the Court adjourned until Monday.

MONDAY, DEC. 3.

The ATTORNEY-GENERAL resumed his address on behalf of the plaintiffs. Continuing to speak of the evidence of Prof. Crookes, he

Digitized by Google

pointed out that Prof. Crookes, amongst other things, objected that the platinum wires would become porous. This, he contended, was an unfair comment on the specification, as it was pointed out in that document that the platinum wires did not go through the glass at all, but were clamped on to the leading wires, which did go through the glass. With regard to the directions as to the use of powdered camphor and oxide of zinc, and the coating with a non-conducting carbonisable material, Prof. Crookes said that these were things which could not be carried out. He was particularly severe as to the powdered camphor and oxide of zinc, which he described as hopelessly misleading directions. Mr. Edison's specification claimed for any fibrous vegetable substance which would leave a carbon residue after heating in a closed chamber. That description was true of every single effective lamp which had ever been used, and it was proved by the evidence of Mr. Swan that what would be a matter of years before Mr. Edison's specification, became a matter of weeks after its publication. It was elicited from the defendants' witnesses that as far as the essential experiments of the Edison combination were concerned, it was a combination which nobody before Mr. Edison had described. The Attorney-General then went on to speak of what occurred before Prof. Stokes, when the defendants again alleged everything to be an impossibility, and required everything to be done over again.

LORD JUSTICE COTTON: They fought hard (laughter).

The ATTORNEY-GENERAL said that the Anglo-American Brush Electric Light Company were manufacturers of these lamps, and no doubt tried everything in their own works.

LORD JUSTICE COTTON: Are the Brush party in attendance?

The ATTORNEY-GENERAL: The Brush Company are defendants. The Brush Company came in as third parties, and defended the action, as having made these lamps. The Attorney-General then proceeded to read the report of Prof. Stokes,* observing that it constituted a very strong commentary on scientific evidence which was being given for the purposes of a case, as compared with scientific evidence which was being given for the purpose of ascertaining the truth. It was impossible in the face of this report to believe the evidence of the defendants' witnesses as to the impossibility of carrying out this process.

LORD JUSTICE LINDLEY: What is the idea in the oxide of zinc?

The ATTORNEY-GENERAL: It was thought it made the material more porous, and gave it greater volume without greater conductivity. The resistance would be the same, but the substance of the filament would be bigger. Mr. Edison's idea was that it would have some effect on the illumination.

In answer to LORD JUSTICE BOWEN,

The ATTORNEY-GENERAL said that one thousand hours was now considered to be the fair life of a lamp, but some of the lamps would, he believed, run for years. A good deal depended upon the stability of the engines running. Experiments were continually being made with a view to making the carbon more lasting. Mr. Swan endeavoured to parchmentise the carbon by removing the cellular development. The earlier lamps ran for perhaps only 150 hours, but that did not affect the validity of the patent; nothing like it had ever been done before. The invention of the filament was, he thought, the most extraordinary step which had ever been made in the history of invention. It was a question of novelty, but that was a question as to which in the previous appeal of Edison *v.* Woodhouse and Rawson.

LORD JUSTICE BOWEN: What is the crucible made of?

The ATTORNEY-GENERAL said it was a plumbago crucible.

Mr. FINLAY said that an ordinary earthenware crucible had also been used.

The ATTORNEY-GENERAL said that no chemist who attempted to carbonise under this specification in a porous crucible could have expected anything but failure, because where the air got in combustion, as distinguished from carbonisation, must take place. Prof. Stokes' report proved to be unfounded and without solid reason every one of the objections taken by the defendants in the course of the case. That which the defendants said never could be done, and was an impossibility, was done in the most ordinary way of carrying out the directions of the specification. There was not one single thing to indicate that in doing that which Prof. Stokes saw done any technical or scientific knowledge, beyond that of an ordinary workman taking the instructions of the specification, was required.

In the course of the trial an admission of an important character was made. That admission was as follows:—"Counsel for all parties admit that running on the pumps or flashing or running on the pumps will materially improve the life of the lamps made at Ponder's End before Prof. Stokes." Flashing was a method of driving out occluded gases well known to Cheesborough and Edison; but the lamps which were tried by Prof. Stokes were tried without any of these improvements having been imposed upon them. The Attorney-General then proceeded to deal with the table of lamps. The lamps made with filaments carbonised in charcoal were unbroken after 30 hours, or five or six working days. This might be thought to be not a long period, but it must be remembered that previous to the specification of Mr. Edison no lamp was known which had any life at all. Lamps with filaments carbonised in sand remained unbroken for upwards of 60 hours. The kaoline filaments were unbroken after 30 to 34 hours' use, and in the case of those with which the zinc oxide was mixed they were unbroken after 40 hours. This was the first time this combination had ever been described, and those lamps were being run under what he might call the dry inexperience of the specification. It could not be contended that because a workman said he could make an improved filament that that was not an infringement. If it were so no lamp could be infringed after it had been improved. In one patent case that was heard before Sir George Jessel the article which was the immediate subject of the patent had never been made at all, because it was shown directly that it could be improved; but the patent still held good and the improvements came under the patent. It was also urged for the defendants that this was a process by which nothing useful could be made; but the lamp was, as a matter of fact, still in use. The Attorney-General went on to read the judgment of Mr. Justice Kay. His commentary upon that judgment was that his lordship delivered it without having in his mind the issues of fact on which the plaintiffs relied. Referring to the comment of the learned judge as to the number of kinds of carbon which could be used, the Attorney-General said that was only an indication of the generality of the invention, which would not at all invalidate it. The various forms of filamentary carbon were all equally good. In the language of Lord Cairns, Mr. Edison in his invention introduced a new integer—that was the carbon filament. With reference to the manufacture of hairpin carbons, the Attorney-General pointed out that Mr. Swan said he had never succeeded at all with a hairpin carbon.

The Court adjourned until the following day.

TUESDAY, DECEMBER 4.

The ATTORNEY-GENERAL, continuing to deal with the judgment of Mr. Justice Kay, said that though the point taken by Mr. Justice Kay was that, having regard to the smallness of the invention, the specification did not give sufficient information as to how the carbon filaments were to be prepared, the plaintiffs contended that it was the use of the carbon filament itself which constituted the new discovery.

LORD JUSTICE COTTON: We all think this was covered by the previous decision, unless the other side can induce us to change our opinion.

The ATTORNEY-GENERAL said the defendants, relying also upon anticipation, called a Mr. Heaviside and another gentleman, whose name he did not recollect, who deposed that in September, 1879, they saw thread lamps or horse-shoe lamps burning in Swan's factory. If that was so that was direct anticipation. They also said these lamps were being run from a gas engine. But it was proved by the evidence of Stearn and Swan that the apparatus which ran those lamps was not put up until 1880, and that Swan and Stearn never made one of those lamps at all until after the fire, which occurred in January, 1880.

LORD JUSTICE LINDLEY thought there was evidently an error of date.

The ATTORNEY-GENERAL said it so happened that Swan had kept Stearn's letters, though Stearn had not kept Swan's letters, because nobody thought the matter would be of any importance. Stearn was a bank manager, and entered into these experiments from a love of electricity. These letters were produced in evidence, amongst them being a letter of Stearn's as late as 1st November, 1879, and one of December, 1879, after the date of the patent, with actual pictures in it of the last development of the lamps that they were then making. As a matter of fact, the first hairpin lamp was mounted by Stearn on 26th November, 1879.

LORD JUSTICE BOWEN: How was the hairpin made?

The ATTORNEY-GENERAL: It was got from Carré; nobody knew how it was made.

LORD JUSTICE BOWEN: You do not know now how it was made.

The ATTORNEY-GENERAL said they did not know now how it was made. It was of about the cross-section of Swan's lamp of 1878; but Swan never made a successful hairpin lamp at all. He submitted that there had been a mistake as to the date, and that the defendants' witnesses really saw in the summer of 1880 what they deposed to having seen in the summer of 1879. He did not feel justified in bringing to their lordships' attention the evidence upon the point which bore upon novelty, but he would give his learned friends notice, in the event of their raising the question of novelty, that he would submit in reply that it showed that the specification was sufficient. If Mr. Justice Kay was right in saying that Edison did nothing to differentiate the Swan lamp of 1878 from that which he was describing in his specification, the answer was that the differentiation was the enunciation of a proposition which indicated absolute success as distinguished from previous failures, and it was not necessary or even proper for a man to go into a detailed method of how he would manufacture his various carbons when he was dealing with the class of filamentary carbons, any one of which would produce an effective lamp; and an effective lamp having been produced the problem is solved. He would ask their lordships to say that if there were brought to bear upon the specification reasonable knowledge and skill, and an intention to work it fairly, the specification was amply sufficient to make this new combination which was described by Mr. Edison. The defendants never said in any part of their case that this was a matter in which direction was required to be given. That was not their case at all. They never took the point which was taken by Lord Justice Lindley, that this work could be done if a proper kind of crucible were adopted. What they said was that it could not be done at all.

LORD JUSTICE BOWEN: That is very true, but the greater includes the less.

The ATTORNEY-GENERAL said he quite agreed that the greater included the less, but his point was that although people knew how to make these filaments, nobody had any idea that this tender thing, which would break in one's fingers if one were not careful, was sufficient to bear the strain of being heated for hundreds and thousands of hours. The people who made the infringing lamps knew what were the practical difficulties of making these filaments, and it could not be suggested that anything depended upon the absence of directions in the specification. What the defendants said was, it cannot be done. More than one of the witnesses said the thing was so absurd they had not even tried it. He would ask their lordships to consider upon this evidence that the process was one which could be carried out. The particular matters as to which the serious attack upon the specification was made would be found on consideration of Prof. Crookes's report not to have been well founded. Going categorically

* See *The Electrician*, July 6th, 1888, p. 269.

Digitized by Google

through the objections taken on behalf of the defendants, it would be found that the things which they said were of no use produced effective working lamps which were to-day perfectly useful, subject only to this one criticism, that they did not last so long and could not be made so cheaply as the newer lamps, in which improved methods of making the carbon had been adopted. If it could be shown that the success of these newer lamps depended upon a departure from Edison's combination, he admitted that his difficulties would be great indeed; but the mere fact of lamps having been improved could not prevent the patentee from having the benefit of the combination which he had described.

Mr. MOULTON proceeded to address the Court.

LORD JUSTICE COTTON: The point upon which we are most anxious to hear you is as to what was the state of knowledge as to carbonisation previous to 1879.

Mr. MOULTON said that carbonisation was a well-known term, and a term denoting a well-known operation producing a well-known result. It meant the exposing of any vegetable matter or any wood to a great heat without letting oxygen get to it. The process which went on was called destructive distillation by some people and carbonisation by others.

LORD JUSTICE LINDLEY: It is roasting out of air.

Mr. MOULTON: It is roasting out of air. These woods were composed largely of hydrogen and carbon. The gaseous matter was driven off and the carbon residue was left. Carbonisation took place in gasworks; the gases being driven off the carbon remained. This was a case where those working at the specification would succeed if they carried out the directions. Nobody suggested that by carbonising a result would be obtained which would not succeed in the lamp. Where such a process as carbonisation was spoken of in a specification it was the duty of persons working according to the specification to use the existing knowledge of the world in regard to that process. If that had been done in this case there could have been no failure. Take, for instance, the process of packing with charcoal. There was no question about the directions as to that process being abundantly sufficient. The absurdity of using a crucible for carbonisation which was porous to furnace gases Mr. Moulton illustrated by saying it was equivalent to corking a cracked bottle.

LORD JUSTICE BOWEN said that if the direction to properly carbonise was sufficient for the ordinary workman the question arose as to what degree of knowledge was to be expected in the ordinary workman. Was he to be a chemist?

Mr. MOULTON said his contention was that it was the duty of the "ordinary workman," whether chemist or not, to make himself acquainted with existing knowledge as to carbonisation. He must, of course, be a man of sufficient knowledge to do the work; he must not be an uninstructed workman. He need not be a man of sufficient capacity to convert an imperfect description into a perfect one; but he should be abreast of the knowledge of the world in regard to the process described. A patent was an invention published to the world, but the publication must, of course, be in plain terms. If it was published in conundrums, or in such technical language that it could not be understood, publication could not be said to have taken place. There was no ground for saying that a person with a willing mind could not have made carbon filaments in accordance with the specification of 1879.

The sitting was largely occupied with reading and commenting upon the evidence, and an adjournment was made until Thursday afternoon.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *November 24th*, 1888.

In spite of the lateness of the season for such work, there has been, and still is, great activity in electrical railway circles in this country. The fact is, the motor companies are so loaded up with contracts that they cannot possibly execute them without a tremendous display of energy in road construction, and the running of their factories at full blast. This week the Thomson-Houston Company, for example, has made public some interesting details with regard to new roads which it has in hand at Wichita, Kan.; Topeka, Kan.; Des Moines, Ia.; Seattle, W.T.; Omaha, Neb.; Cleveland and Alliance, O.; Louisville, Ky.; Danville, Va.; Syracuse, N.Y.; Boston, Mass.: Ansonia, Ct.; Bangor, Me.; and Scranton, Pa. I understand that the company has further contracts, but it will be admitted that these in themselves are enough to keep any concern busy, especially when most of the roads are required to start before the snow flies. The Omaha road, which has already been put in operation, with 16 motor cars and 16 plain passenger cars, is unique in having a feature possessed by no other street railway in the world. The road runs from Omaha to Council Bluffs, and is nine miles long, and the cars are of the type known in this country as the "vestibule," built by the Pullman Palace Car Company. In this style of car, with doors at each end, as in the ordinary railroad car, the passage-way formed by the platform of the two cars is housed in with leather, and cloth sides and top, which close and expand like a concertina. In this way the traveller can go from one end of the train to the other, no matter what the weather and the rate of speed, without being in the slightest way exposed or inconvenienced. The application has been very popular on the steam roads, and I have no doubt that it will prove equally so at Omaha, where the severity of the winter is such as to render protection against the elements highly welcome. A yet fuller idea of the magnitude of the enterprise, and the pains bestowed upon it, may be formed from the fact that the road includes a fine bridge, 3,000ft. long, across the Missouri River. If anybody is in doubt as to the prospects of electric railroads, I think I can do no better than refer him to such enterprises as this, which represent the investment of hundreds of thousands of dollars. Another large new Thomson-Houston road is that at Wichita, Kansas, and an even more important undertaking is that at Topeka, in the same State, which will have, when complete, 700 horse-power of generators. The same company has two other new large contracts, those for Cleveland and Louisville, in each of which forty cars will be required. The Sprague Electric Company are also extremely busy on railway work, enlarging old roads and adding new ones to their list. The work at Boston is being pushed forward with all possible speed. A large road has just been started at Akron, Ohio, and another at Lafayette, Indiana; while the operation of the road at St. Joseph, Mo., during the recent tremendously heavy snowstorm, has been most encouraging. In this last case, though the storm practically paralysed all the other means of electrical service, the conductors of the electric railroad stood up bravely, and the cars made their regular trips without delay or stoppage. Every opponent of electric railroads has been saying, with a significant nod, "just wait till winter comes." Well, winter has come, and the roads are doing their work in a much better manner than even their friends anticipated. It really seems wonderful what an electric car can be made to go through when it has a stout motor on it, and the generating capacity of a big station behind it. With regard to the Sprague road at Harrisburg, Pennsylvania, a very flattering report is made by the management. There are now five cars running over five miles of track eighteen hours a day. During the month of September the cost of operating such a service was $1,200; that sum including everything of every nature. The receipts were $3,600, showing a net profit for the month of $2,400, or 30 per cent. per annum on the capital stock. From the Lykens Valley coal mines, where the Schlesinger system has been in operation, another good report comes. One of the motors there a few days ago hauled out 34 loaded cars, representing a total weight of 2,000 mile-tons. The satisfaction given by the plant is shown by the fact that it has been paid for. Altogether, I think it may be said that the outlook for electric railways was never so good, and that great as has been the extension of business during the past year, the growth during 1889 will be infinitely greater.

American electrical manufacturers are gradually becoming accustomed to look upon the West Indies and South America as a good market for their wares. This is particularly the case at the present time with regard to electric lighting, and I am inclined to think that considerable business is being done. One of the largest operations at the present time is that connected with the Island of Cuba, where a franchise has just been granted, by the municipal authorities of Havana, to a company which proposes to light that city, and to do an indoor business as well. The company is supported by American capital and enterprise, and there are good reasons for thinking that the field in Havana will prove a profitable one. But outside of Havana and the other cities, like Santiago-de-Cuba, there is plenty of unworked ground in connection with the various industries, such as the tobacco works, the sugar plantations, and the copper mines. In many parts of the West Indies and Central America there are fine water powers, and as soon as it is ascertained that they are sufficiently stable to be depended upon the year round, there will be a widespread introduction of electric lighting apparatus from this country. In some instances such water power has already been utilised, and the results have been very gratifying.

Speaking of water power reminds me of an enterprise which has just been organised in another part of this hemisphere, that to the north of us. One of the great scenic attractions of the

Digitized by Google

fair city of Montreal is the Lachine rapids, and I daresay many of your readers will recall pleasant and exciting hours spent in their neighbourhood. For some time past there has been agitated the question of utilising the water power which is developed on the St. Lawrence in connection with these rapids, but so far nothing has been done. It is now reported from Montreal, however, that a syndicate has purchased the Ile au Heron, and will use the water power there developed for electric lighting in the city. It is asserted that 250,000 horse-power will be available. The building of the dam, bridges, &c., will begin at once, and the cost of the work is placed at about £100,000. It is said that English, as well as Canadian and American capital, is interested. The local Edison Electric Light Company is understood to have quite an active part in the matter. It will be very interesting to watch the execution of this work, not simply for its own sake, but for the bearing it may have on other plans in Canada of an even more extensive character, such as utilising part of Niagara, for example.

It has been quite a popular practice to use the electric light in connection with festivals and sports at night time, and some of our largest areas in the country devoted to athletics, &c., are well supplied with arc lights. An amusing incident which occurred in this city during the past week shows, however, that where football kicking is included in the programme it is well not to have any arc lights in the way. One of the competitors succeeded in putting the ball plump up against one of the lights, shattering it completely, and he followed up this performance by smashing another light, though not so badly. This may be a good way of showing the accuracy of a man's kicking, and perhaps the idea may be utilised in obtaining an exact record of the height of the kick, but it is certainly very hard on the lamps. A big arc light is such an attractive thing that one cannot greatly wonder at its being made a mark of, and it is even asserted that the pernicious activity of our street boys does much to promote the prosperity of the glass factories. Electric lighting is not the only industry of the kind that thus suffers. Out West, as you have probably heard before, it is a constant amusement with the cowboys to use the glass insulators along the telegraph lines as targets, matching each other on the result, so that they often break themselves, the record, the insulator, and the circuit all at once.

CORRESPONDENCE.

SIR WILLIAM THOMSON'S SIMPLE HYPOTHESIS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In a Paper read before the British Association, at Bath, Sir W. Thomson proposed the following equations for a field of incomplete circuits:—

$$u=\frac{1}{\kappa}\left\{\nabla^{-2}\frac{du}{dt}-\frac{d\psi}{dx}\right\};\quad v=\frac{1}{\kappa}\left\{\nabla^{-2}\frac{dv}{dt}-\frac{d\psi}{dy}\right\};$$

$$w=\frac{1}{\kappa}\left\{\nabla^{-2}\frac{dw}{dt}-\frac{d\psi}{dz}\right\};$$

$$V^2\left(\frac{du}{dx}+\frac{dv}{dy}+\frac{dw}{dz}\right)=\frac{d}{dt}(\nabla^2\psi),$$

where $\frac{1}{4\pi\kappa}$ is the conductivity, V is the number of electrostatic units in the electro-magnetic unit of electric quantity, and the remaining symbols have their ordinary meaning.

These equations give, κ being constant—

$$\frac{\kappa}{V^2}\frac{d}{dt}(\nabla^2\psi)=\frac{1}{V^2}\cdot\frac{d\psi}{dt^2}-\nabla^2\psi$$

$$\nabla^2\psi+\frac{\kappa}{V^2}\cdot\frac{d}{dt}(\nabla^2\psi)=\frac{1}{V^2}\cdot\frac{d^2\psi}{dt}$$

$$\kappa\nabla^2 u=\frac{du}{dt}-\frac{1}{4\pi}\cdot\frac{d}{dx}\nabla^2\psi.$$

Maxwell's equations give—

$$\nabla^2\psi+\kappa K\frac{d}{dt}(\nabla^2\psi)=0,$$

$$\kappa\nabla^2 u=\left(1+\kappa K\frac{d}{dt}\right)\left\{\frac{du}{dt}-\frac{1}{4\pi}\frac{d}{dx}\nabla^2\psi\right\}.$$

K is a quantity of the order $\frac{1}{V^2}$, and both K and $\frac{1}{V^2}$ are so small that unless the operator $\frac{d}{dt}$ increases the quantity operated upon in a ratio comparable with the velocity of light, the two sets of equations give results sensibly identical.*

Unless, therefore, we can explore the field with instruments of such delicacy as to detect the existence of electromagnetic actions, oscillating with a rapidity comparable with that of light vibrations, we have no experimental evidence enabling us to form any decision between Sir W. Thomson's and the Maxwellian theory.

Thus, in the field of a leaky condenser, mentioned by Prof. Poynting in *The Electrician* a few weeks back, the absence of any observed magnetic force does not go far to prove Maxwell's view, although its presence would be conclusive against it.

In fact, Sir W. Thomson's field is one in which the currents are, *ex hypothesi*, confined to the conductors, and in those conductors satisfy the equation

$$V^2\left(\frac{du}{dx}+\frac{dv}{dy}+\frac{dw}{dz}\right)=\frac{d}{dt}\nabla^2\psi,$$

and, therefore, unless $\frac{1}{V^2}\cdot\frac{d}{dt}$ be finite, *i.e.*, unless the forces in the field be oscillating with the rapidity of light vibrations, u, v, w, sensibly satisfy the equation

$$\frac{du}{dx}+\frac{dv}{dy}+\frac{dw}{dz}=0.$$

Maxwell's field is one in which the conduction currents satisfy the conditions $\frac{dp}{dx}+\frac{dq}{dy}+\frac{dr}{dz}=\kappa K\frac{d}{dt}\nabla^2\psi$,

i.e., sensibly $\frac{dp}{dx}+\frac{dq}{dy}+\frac{dr}{dz}=0$,

with the above mentioned limitation as to $\frac{d}{dt}$.

And the displacement currents in the conductor and the surrounding dielectric are insensible in comparison with the conduction currents in the conductor being to them in the ratio

$$k K\frac{d}{dt}\cdot \text{P to P}$$

where P is the electromotive force.

The two fields, therefore, are sensibly the same, and the theories merely differ in the fact that one, rightly or wrongly, leads to a magnetic theory of light and the other does not.—

Yours, &c.,

H. W. WATSON.

Berkswell Rectory, Coventry, November 26, 1888.

THE ELECTRO-MAGNETIC EFFECTS OF A MOVING CHARGE.—II.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: All disturbances being propagated through the dielectric ether at the speed of light, when, therefore, a charge is in motion through the medium, the discussion of the effects produced naturally involves the consideration of three cases, those in which the speed u of the charge is less than, or equal to, or greater than v, that of light.

In a previous letter under the above heading (*The Electrician*, Nov. 23, 1888, p. 83), I gave the complete and very simple solution of the intermediate case of equality of speeds. A formal demonstration is unnecessary, as the satisfaction of the necessary conditions may be immediately tested.

But I was not then aware that the case $u < v$ admitted of being presented in a nearly equally simple form. That such is the fact is rather surprising, for it is very exceptional to arrive at simple results, and these now in question are sufficiently free from complexity to take a place in text-books of electricity.

Let the axis of z be the line of motion of the charge q at speed u. Everything is symmetrical with respect to this axis. The

* If κ be so large that $\frac{\kappa}{V^2}$ in the Thomson field, or κK in the Maxwell field, be of sensible magnitude, then u in the former and p in the latter become insensible.

Digitized by Google

lines of electric force are radial out from the charge. Those of magnetic force are circles about the axis. The two forces are perpendicular. Having thus settled the directions, it only remains to specify their intensities at any point P distant r from the charge, the line r making an angle θ with the axis. Let E be the intensity of the electric and H of the magnetic force. Then, if c is the permittivity and μ the inductivity, such that $\mu c v^2 = 1$, we have

$$(u<v)\begin{cases} cE = \dfrac{q}{r^2}\dfrac{1-\frac{u^2}{v^2}}{\left(1-\frac{u^2}{v^2}\sin^2\theta\right)^{\frac{3}{2}}} \quad \ldots \quad (A) \\ H = cEu\sin\theta \quad \ldots \quad (B) \end{cases}$$

That (A), (B) represent the complete solution may be proved by subjecting them to the proper tests. Premising that the whole system is in steady motion at speed u, we have to satisfy the two fundamental laws of electromagnetism :—

(1.) (Faraday's law.) The electromotive force of the field in any circuit equals the rate of decrease of the induction through the circuit (or the magnetic current $\times -4\pi$).

(2.) (Maxwell's law.) The magnetomotive force of the field in any circuit equals the electric current $\times 4\pi$ through the circuit.

Besides these, there is continuity of the displacement to be attended to. Thus :—

(3.) (Maxwell.) The displacement outward through any surface equals the enclosed charge.

Since (A) and (B) satisfy these tests, they are correct. And since no unrealities are involved, there is no room for misinterpretation.

When u/v is very small, we have approximately

$$cE = \frac{q}{r^2}, \qquad H = \frac{qu}{r^2}\sin\theta,$$

representing J. J. Thomson's solution—that is, the lines of displacement radiate uniformly from the charge, and the magnetic force is that of the corresponding displacement currents together with the moving charge regarded as a current element of moment qu. Instantaneous action through the medium is involved—that is, to make the solution quite correct.

That the lines of electric force should remain straight as the speed of the charge is increased is itself a rather remarkable result. Examining (A) we see that the effect of increasing u is to concentrate the displacement about the equatorial plane $\theta = \frac{1}{2}\pi$. Self-induction does it. In the limit, when $u = v$, the numerator vanishes, making $E = 0$, $H = 0$ everywhere except at the plane mentioned, where, by reason of the denominator becoming infinitely small in comparison with the numerator, the displacement is all concentrated in a sheet, and with it the induction, forming a plane electromagnetic wave, as described (and realised) in my previous letter.

If we terminate the field described in (A) and (B) on a spherical surface of radius a, instead of continuing it up to the charge q at the origin, we have the case of a perfectly conducting sphere of radius a possessing a total charge q, moving steadily at speed u through the dielectric ether. As the speed is increased to v, the charge all accumulates at the equator of the sphere.

But after that? This brings us to the third case of $u > v$, and here I have so far failed to find any solution which will satisfy all the necessary conditions without unreality. The description at the close of my previous letter must therefore be received as a suggestion at present unconfirmed. I hope to consider the matter in a future communication.—Yours, &c.

OLIVER HEAVISIDE.

P.S.—In a recent number Mr. W. P. Granville raised the question of action through a medium being only action at a short distance instead of a long one, and asked for instruction. His inquiry has elicited no response. This is not, however, because there is nothing to be said about it. The matter did not escape the notice of the "anti-distance-action sage." My own opinion is that the question involved is, if not metaphysical, dangerously near to being so; consequently, whole books might be devoted to it. At present, however, I think it is more useful to try to find out what happens, and to construct a medium to make it happen; after that, perhaps the matter referred to may be more advantageously discussed. The well of truth is bottomless.

ELMORE'S ELECTRO-BURNISHING PROCESS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I read in *The Electrician* of November 16 a very interesting article on the electrical properties of copper wire made by Elmore's electro-burnishing process, but I regret that there was no mention of how the conductivity was determined. There are two ways, giving results quite different, as M. Mialaret (ingénieur des poudres et salpètres) indicated in a communication to the Société Internationale des Electriciens last year. In the first, the conductivities of two wires of the same length and section are compared; in the other, the conductivities of two wires of the same length and weight are compared. The first method is the more rational, and always gives a higher conductivity than the second. Thus, I read in an article of M. Hospitalier, in *l'Electricien* of July 16, 1887 :—

High Conductivity Wire from Bogny (Ardennes).

	No. 1.	No. 2.	No. 3.
Density	8·897	9·32	9·6
Conductivity, equal volume	102·4	106·7	110·8
Conductivity, equal weight	101·7	101·2	101·6

It is therefore of the greatest importance to mention if the conductivity has been taken for equal volume or for equal weight. You would oblige me very much by indicating this as regards Elmore's copper.

To obviate this confusion it would be better to indicate the specific resistance or the specific conductivity in microhms-centimètres or in mho per centimètres.—Yours, &c.,

GASTON ROUX.

Préparateur de M. Hospitalier à l'Ecole de Physique et de Chimie Industrielles, 51, Rue de Dunkerque, Paris.

CABLE-TESTING—COPPER AND DIELECTRIC RESISTANCE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reply to your correspondent "Megohm," I wish first to thank him for his doubtless well-meant intentions in pointing out the error existing in my figures, as published, for the relative effects of pressure and temperature on gutta-percha at 2,000 and 3,000 fathoms depths. It would naturally, I imagine, be apparent that this was only a "slip," as I had already referred to the fact (attained from Sir William Siemens' experiments) that the resistance was increased at a rate directly proportional to the amount of pressure exerted. I did not observe the error (as I ought to have done) until reading over my remarks in your issue of November 16th. It does not, however, alter the general inference that the greater the depth the larger is the share which pressure takes in proportion to that taken by low temperature in increasing the resistance on submergence, though it materially defers the depth at which the pressure has an equal effect on the resistance of gutta-percha with that of the bottom temperature. My example was, however, only intended to give an illustration of the comparative effects of pressure and temperature at various depths. Had it been intended for anything more I should not have spoken of it as the effect produced on gutta-percha *generally*, but, rather, on a particular gum of the same. In referring to the matter further I should have required to state the manner in which the different gums of gutta-percha are affected by the temperature at any depth. For instance, the resistance of some gutta-percha gums (just supposing that they also, at some different degree of age, had a resistance of 600 megohms at 75°F.) would be increased from 600 megohms at 75°F. to 11,641 megohms at 36°F., instead of to 6,737 megohms, as in the case given; whilst that of other qualities would become only 3,373 megohms by the same decrease of temperature.

As regards the other points brought up in your correspondent's letter, I still fancy that 102·38 per cent. is, at the present time, "quite an ordinary conductivity for copper intended for telegraphic purposes;" neither do I think it "will come somewhat

Digitized by Google

as a surprise to those engaged in the testing or manufacture of cables," as suggested by your correspondent.

In stating that "the correct coefficient for variation of resistance by temperature is frequently somewhat higher than that given for Dr. Matthiessen's standard, I referred to each particular coil, and not, as your correspondent appears to suppose, to any entire length of cable, in which he rightly points out "an average conductivity of 98 or 99 per cent. is generally considered an excellent result;" 96 per cent. is usually about the conductivity stipulated for in specifications for each "hank" of copper wire composing a submarine cable. I did not wish to be understood that the *average* conductivity was as high as 102·38 per cent., but that inasmuch as such conductivities above 100 per cent. occur frequently amongst the "hanks" of wire, the correct coefficient for temperature would be frequently above that given for Matthiessen's standard pure copper, and on a complete cable the average conductivity is, therefore, often as high, or possibly even slightly above, that of Matthiessen's standard; therefore, it is not unlikely that the absolutely correct temperature coefficient of the conductor would be often as high as (or sometimes even higher than) that for the standard copper. As long ago as in 1883 Mr. Willoughby Smith, in his Presidential Address to the Society of Telegraph-Engineers, gave results of experiments on the conductivity of various samples of copper wire, in which some showed themselves to have a higher conductivity than Matthiessen's standard. Commenting on the same, Mr. Smith said, "These results confirm what I have already mentioned, that some commercial copper has a higher specific conductivity than the long recognised standard for pure copper." If conductivities of 101·4 per cent. were attained in 1883 (instead of 50 per cent. in 1858), it is only natural that such conductivities as 102·4 per cent. should not be uncommon nowadays. In point of fact, if your correspondent tested the copper wire of a certain French firm, he would not, I fancy, find any samples with a conductivity below 101 per cent.

Previous to your correspondent's remarks, I was not aware that a doubt existed as to the desirability of a fresh copper standard being before long adopted.

Your correspondent implies that I suggested that the temperature coefficient for the resistance of the copper conductor should be *determined* by observing its resistance at various temperatures, as denoted by variations in the resistance of the gutta-percha dielectric of any cable. It certainly was not my intention to suggest any such notion.

What I wanted to point out was, that when an opportunity presents itself of observing the resistance of the gutta-percha dielectric as well as of the copper conductor at wide ranges of temperature of known degrees, it was useful to do so, as in the case when a cable is taken out from England in the winter at an atmospheric temperature of, say, 35°F., and passes through the tropics in a water (tank) temperature of 85°F., and then afterwards, in going south, experiences a temperature of, say, 32°F., and then again an equatorial temperature of 80 to 90°F. In the first place, the opportunity is one which it is well to take advantage of (from a scientific interest point of view, at any rate,) in order to observe the rate at which the resistance of gutta-percha answers to a change of temperature of known degree as compared with that of copper. Where a cable is coiled in the tanks aboard ship the temperature of the water may be noted, and after a change in the temperature of this water it is useful to note how soon the copper picks up that temperature (as regards its electrical resistance), and how soon the gutta-percha does so. It might in some ways naturally be supposed that, the copper conductor being enveloped inside the gutta-percha insulator, the gutta-percha would, especially in the case of a laid cable, the soonest adapt itself to any alteration in the prevailing temperature. This does not, however, appear to be the case; in fact, the gutta-percha, as a rule, lags uniformly behind the copper in this respect by about 48 hours. That is to say, in the case of a fall of temperature of 30°F. the gutta-percha of a core would not give its true resistance exactly corresponding to this decrease of temperature till about 48 hours after the copper has done so. This is, very probably, owing to the fact that in the case of gutta-percha the effect of a change of temperature is (by increasing or decreasing its density) that of gradually driving out or absorbing moisture, and thus gradually increasing or decreasing its electrical resistance, whereas in that of a metal it is merely that of altering its degree of homogeneousness. Moreover, on a long outward voyage, passing through a large variation of temperature, by noting the insulation resistance at each of these temperatures as they respectively recur at various stages of the voyage, the variation of resistance due to age can be approximately determined, and the altered degree of variation of resistance due to each variation from the standard temperature (owing to the alteration in specific resistance by age) can be determined for the cable when about to be laid. In this way useful curves may be drawn up showing the variations of resistance by age, and that by temperature of different gums of gutta-percha; and others showing the respective variations by temperature of the said gums at various periods since manufacture of the core.

Inasmuch as gutta-percha takes so much longer to answer to a change of temperature (or become "temporised," as I have heard a jointer express it) than copper does, it might in some cases (as in that of a cable just laid in very cold water) be inaccurate in reducing the observed dielectric resistance to that at 75°F. to correct the resistance by the temperature calculated from the conductor resistance, owing to the fact that the gutta-percha may not have yet adapted itself (as regards its resistance) to such a low temperature as the copper has. Under these circumstances it is sometimes a little useful (even in practice) to calculate the temperature of the dielectric from its resistance, as an additional check on that attained for it by the resistance of the conductor, and, at intervals, by the thermometer. This only is what I wished to imply in my previous remarks on the subject. In this case the effect of the pressure on the resistance of the gutta-percha at that depth would, of course, however, require to be included in the calculation. Your correspondent appears to have unwittingly misunderstood me in this matter, or else he has a partiality for the practise of setting up a figure in order to knock it down again by a process of fertile imagination indulged in, as a rule, only by writers of fiction.—Yours, &c.,

November 28th. CHARLES BRIGHT.

[The above letter arrived too late for last week's issue.—ED. *E.*]

"THE CONDUCTION OF ALLOYS AND SOLID SULPHIDES."

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Your issue of November 16th contained an abstract of a Paper on the "Conduction of Alloys and Solid Sulphides," by Dr. Gladstone and myself. In one respect the abstract is misleading, as it suggests that one of our experiments leads to conclusions opposed to those of Prof. Roberts-Austen.

Our method was to pass a current through a fused alloy in a U-shaped tube, and to see if the ratio of the resistances of its arms altered when a current passed through. The method evidently assumes that there would be a change of resistance if the current caused a change of composition.

To test this assumption in some degree, we slightly changed the composition of one arm by adding a small percentage of lead, and found a very appreciable change in the resistance ratio. But this change was due to the added lead, and was a justification, so far as it went, of our assumption. Your abstract misleads by suggesting that it was a proof of electrolytic conduction.—Yours, &c., W. HIBBERT.

4, Albert-terrace, Notting Hill-gate, W., Dec. 5, 1888.

THE STANDARD CONDUCTIVITY OF COPPER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The Exchange Telegraph Company is to be congratulated on having been able to obtain such high conducting copper for its lines so long ago as fifteen years. Great care must evidently have been taken in its manufacture, or else it was a piece of singular good fortune.

Digitized by Google

It is a matter for regret that this high standard has not been maintained, as at the present time the large cable companies consider 98 or 99 an excellent result.

The four sections of the West African Cable Company's line, laid in 1886, have an average conductivity of 97·84, and the seven sections of the African Direct Company's line, laid in the same year, have an average conductivity of 98·2.

Occasionally now when great care is taken in melting electro-deposited copper, some excellent "wire bars" are turned out, and the average conductivity of 98 to 99 is surpassed; but this (usual) method of manufacture cannot be relied on to produce uniformly good results, a conclusion which is emphasised by the above-quoted cable conductivities.

One great advantage (amongst others) of the new process mentioned by Mr. Lant Carpenter in his Paper is that the copper can be absolutely relied upon to *always* possess the high conductivity quoted by him.—Yours, &c., C. J. S.

December 5, 1888.

THE COUNCIL OF THE SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The voting papers of the Society of Telegraph-Engineers and Electricians are now in the hands of members, and to telegraph men cannot but afford matter for painful reflection. Here is a society initiated, maintained, and made a success chiefly by telegraph-engineers, and yet things have come to such a pass that neither in the Council itself, nor in the list of members recommended by the Council for election, is there a single representative of purely telegraph work. Among the past presidents alone can any such be found, and these it is out of the power of our Council to supersede. As no new members are being added to the list, the time is not far distant when, if we do not take the matter into serious consideration, telegraphy will be entirely ignored. The very name of the Society is about to undergo "rectification," so as to extinguish the last faint glimmer of what was once a powerful factor in the scientific world.

Ten years ago this Society had on its Council such names as Scudamore, Latimer Clark, Preece, Walker, Webber, Willoughby Smith, Bright, Forde, Varley, Andrews, &c. To-day, except among the shelved presidents, there is not a single name known to telegraphy. One by one they have been weeded out, evidently in pursuance of a fixed policy, until recently the last connecting link between the old Society and the collection of professors now in power was ousted so rudely that he withdrew from the Society altogether; I refer to Mr. W. T. Ansell, whose action in this instance many of his friends deplore. He ought to have stuck to his guns for the sake of the principle involved. The telegraph interest is surely strong enough and important enough to insist upon due representation in its own Society, and we ought not to permit our share in the Society to pass out of our hands, if only for the sake of our inheritance in the Ronalds Library, which was left to the telegraph-engineers. The Society was made by telegraphy, and it is not creditable that in an electrical institution room cannot be found for a branch of the science which has done more to benefit humanity and promote the progress of the world than any other agency in the present century.—Yours, &c., TELEGRAPHY.

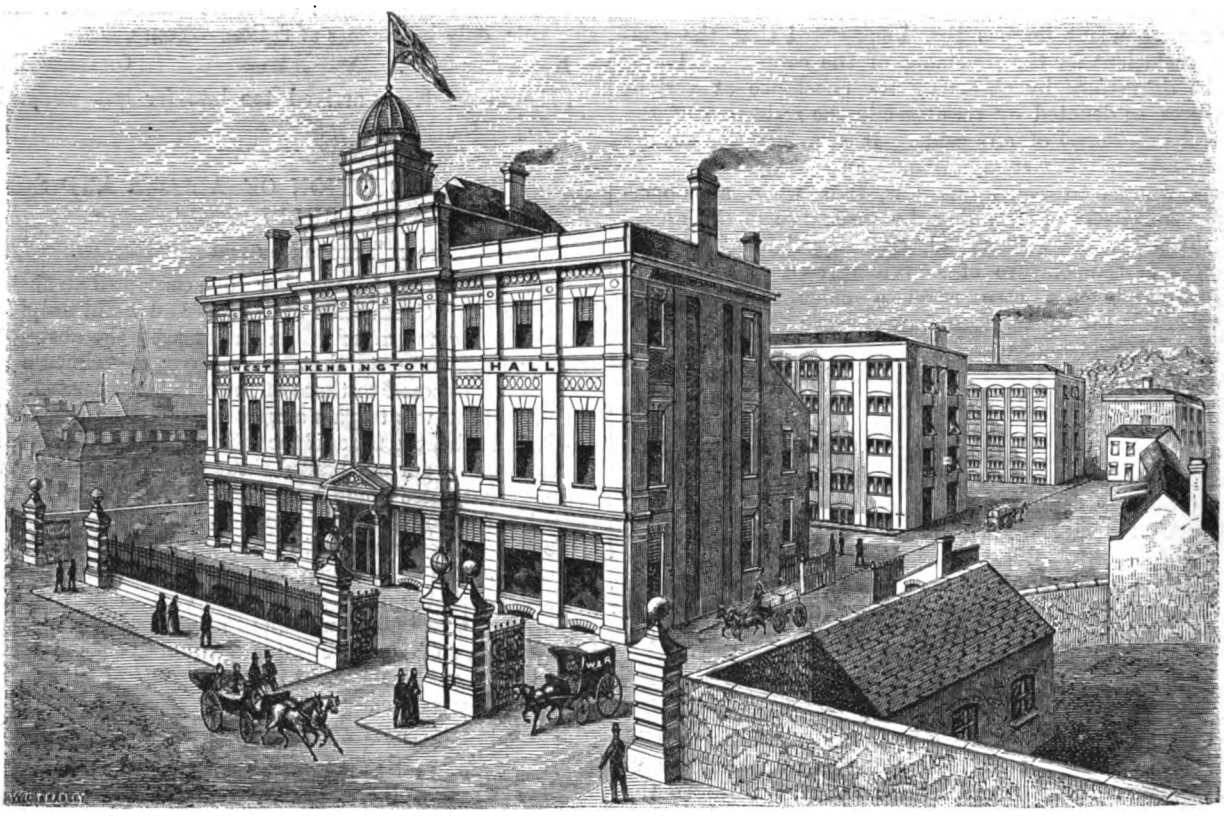
TELEPHONE CALL OFFICES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Referring to my letter of last week, I have now ascertained that the call office at Hall's, in Edinburgh, was opened on the 26th July, 1880. This office was then, and still is, a public one.—Yours, &c., F. FAITHFUL BEGG.

6, Drapers'-gardens, December 4, 1888.

THE WORKS OF THE WOODHOUSE AND RAWSON MANUFACTURING COMPANY AT WEST KENSINGTON.



The above illustration shows a view of the works of the Woodhouse and Rawson Electric Manufacturing Company (Limited). It may be recollected that a few weeks ago (*The Electrician*, August 24, 1888,) we gave a description of the above works. At that time the large block of buildings facing the street was only partially occupied by the company, but we understand that very shortly the whole of the premises—which are at present owned by two of the shareholders—will become the property of the company. We may mention that Messrs. Woodhouse and Rawson have recently received an order for over 100,000 switches; this is probably the largest order for switches ever given out. It is the manufacture of articles on a scale such as this that enables high quality to be supplied at a low price, and we are glad to see such orders, as it affords satisfactory evidence of the progress of electric lighting industry.

Digitized by Google

ELECTRIC LIGHTING AND THE KENSINGTON VESTRY.

The Special Committee of the Kensington Vestry upon Electric Lighting at a recent meeting recommended that the Vestry do refer back to the Committee the report of the 13th November, with a view to its further consideration. Mr. Lindsay had given notice of his intention to move :—

"*That the Committee be instructed to report how far the Vestry can arrange with the various companies applying for Licenses or Provisional Orders for electric lighting in Kensington, so as*—(a) *To prevent any one company having a monopoly of any one district, and so as to prevent more than two companies obtaining power to open any one street;* (b) *To prevent the erection of overhead wires, except as a temporary expedient, with the consent of the Vestry, and to ensure the taking down within three years of any such overhead wires as may be temporarily permitted;* (c) *To prevent any claim arising on the part of any company for damage done to underground wires on the occasions of the roads being repaired, unless such damage be caused wilfully or by unworkmanlike conduct of persons in the employment of the Vestry, also that the Committee be instructed to inform the Vestry, as far as practicable, in relation to any company in favour of which they may recommend that the Vestry should consent to the granting of a License or Provisional Order :*—(a) *What is the paid-up capital of such company subscribed by* bonâ fide *shareholders?* (b) *Where such company has, or proposes, to erect its machinery?* (c) *What amount of electric light has been hitherto supplied, and in what place or places, by any such company?* (d) *Whether any such company itself undertakes the preparing the internal arrangements of premises for the reception of the electric light, or what conditions any such company is accustomed to make in relation to this matter.*"

Mr. LINDSAY reminded the Vestry that on the last occasion the committee brought up a report dividing Kensington into four areas, and giving to four companies a monopoly of those areas. An amendment was carried, going to the root of the matter, that the Vestry objected to any monopoly. There was considerable dismay on the part of the committee when that was carried, and he felt that himself and others were bound to show that the view they took was a practical one. He must admit that the members of the committee had given a vast deal more time and attention to the subject than he had, and were much better versed in details, therefore he only ventured to oppose them on a matter of principle, and he asked the Vestry to assist the committee by stating whether they do or do not agree with the views set out in his notices. Anything the committee would have to consider would apply to Prosional Orders only, as no Licences will be granted this year. He had been informed of two facts which the committee ought to have told the Vestry—one was that the London Electric Lighting Company had offered to supply the whole light for Kensington at wholesale price and allow the Vestry to make a retail profit. There might be very strong arguments against that, but he said the Vestry ought to have been told of it. After that was refused, the directors asked the Vestry to visit their works, in order to see whether or not they were competent to carry out what they proposed, but received a curt reply that they had not time to visit Deptford, though they could go to Eastbourne. It was suggested at the last discussion that those companies only should be allowed to light Kensington which had their stations in the parish, in order to facilitate the purchase of the works at the end of 21 years, and he contended that was a ground the Vestry ought not to adopt. Not only was that contingency very remote, but if anything is absolutely certain, it is that local government will be so perfected as to utterly obliterate local authorities so far as the supply of light is concerned. Moreover, the first Act was passed with that provision for the sale of works in 21 years, and under that it was found impossible to get the necessary capital subscribed; the Legislature, therefore, by a new Act, enlarged the time to 42 years, yet the committee decided to make a condition of that which Parliament said should not be a condition. If companies were willing to give up their rights in 21 years, it led to the inference that they were not financially strong, and wished to obtain a concession which would make them stronger, and the Vestry should be especially careful not to give such companies a monopoly. Another point was that if any company made it a condition that they alone should put up the machinery in houses for the light, it pointed to their desire to make a very large profit out of that alone, and they might probably after that give little consideration to fulfilling their obligations to supply the light. He said emphatically that he had no personal interest in any lighting company, but he did wish to secure for all fair consideration by the Vestry. He denied the right of the Vestry to say that consumers should obtain their light only from this or that company, and they would be travelling out of their province to make any such arrangement. Mr. Lindsay concluded by moving the adoption of the instructions given above.

Mr. TORR supported the motion, and opposed the idea of a monopoly, saying that the only possible condition when it could be endured was when it was in the hands of municipal bodies themselves for their own benefit.

Mr. WILSON said the first steps taken by the committee were to prevent monopoly, and there had been no single point raised in the discussion which had not been fully thrashed out in committee. It was unfortunate, perhaps, that their report had been sent in at so short a notice, for had it been amplified, what they had done would have appeared in a very different light, but from want of that the committee had been harshly judged.

Mr. DUFFIELD supported the action of the committee, and said if the instructions were passed, ratepayers would not have electric light for years.

Mr. SAUNDERS, Mr. BRAYE, and other members having spoken in support of a reference back,

Mr. LINDSAY said if the committee would be good enough to consider his suggestions, he would not move them as instructions; but he asked that they would again receive, and perhaps cross-examine, representatives of the different companies.

The matter was then referred to committee, by consent, for further consideration and report.

COMPANIES' MEETINGS.

The Maxim-Weston Electric Company (Limited).

An extraordinary general meeting of this Company was held at the City Terminus Hotel, Cannon-street, on Monday last, under the presidency of Mr. John Marks.

The SECRETARY (Mr. Samuel J. Boyce) having read the notice calling the meeting, and the resolutions proposed to be submitted,

The CHAIRMAN said that part of the business that they were met there to discuss was of a contentious character, if he might be allowed to use the term, and part of it was of a non-contentious nature. With regard to the first resolution—to voluntarily wind up the Company and appoint certain people liquidators—he purposed asking the shareholders to be good enough to divide it into two resolutions, for this reason, that the first part of that resolution he would make a resolution entirely by itself—that was to say, that the Maxim-Weston Company be wound up voluntarily, because it seemed to be pretty unanimously agreed that it was necessary that the Company should be wound up. As a matter of fact it must be wound up, because they could not continue. On that head he did not think there would be any opposition to the suggestion of the Directors. But he could gather that there would be some opposition to the appointment of the liquidators, from a circular that Mr. Hugh Watt had issued, in which that gentleman advocated the appointment of a high-class liquidator. He thought, therefore, that it would conduce to the despatch of their business if they dealt in the first place with what he surmised there would be no opposition to, namely, the resolution to wind up the Company voluntarily, and to take the second part of the resolution dealing with the appointment of the liquidators as a separate one. They would recollect that at the last meeting they held for the confirmation of the reduction of the capital it was arranged that, unless 80,000 of the unissued shares were applied for, the Directors would make no allotment. Those 80,000 shares were not applied for—not many more than one-fourth of that number having been applied for—and therefore they did not and could not, in fact, owing to their engagement to the shareholders, proceed to make any allotment; but they returned to the shareholders the money paid on application. The result of the shareholders not coming forward and taking up the minimum number of 80,000 shares was, that the capital that was necessary for the carrying on of the business had not been provided, and consequently there was no help for it but to wind up voluntarily; therefore, he begged to move formally—

"*That the Maxim-Weston Company be wound up voluntarily.*"

In doing that he left ample opportunity for any gentleman to address the meeting on the subsequent resolution, unless there were any gentlemen prepared to propose a direct negative to the one now proposed.

Sir HENRY HOARE seconded the motion.

A SHAREHOLDER said that the Chairman had referred to a circular sent out by Mr. Hugh Watt, but he (the speaker) had neither seen nor heard anything of the kind.

The CHAIRMAN replied that Mr. Watt had favoured only a few of the shareholders with a copy of the document in question.

Mr. BOWYER, as one of the original shareholders of the Company, said he would like to know whether an explanation could be given of the steps that were to be taken to induce a further inquiry into the conduct of the Member of Parliament who was their Chairman with regard to the disposal of the Company's assets, which had been disposed of in a very mysterious manner. Owing to the meagreness of the reports that had been published, those who had not attended the meetings had not been able to gain any information as to what had been done in the matter. He would like to know whether the accountants who had passed those very extraordinary accounts should not be brought to book for it. There seemed to have been some very strange conspiracy somewhere, and he thought some inquiry ought to be instituted, and fairly and fully reported, so that they might know the exact state of the case.

The CHAIRMAN replied that the subject was at present before a court of law, and he would not feel himself justified in anticipating the action. It had not been lost sight of by the Board, who fully agreed with the shareholders that the whole matter of the accounts should be investigated. Entertaining that opinion, they had commenced an action against Mr. Watt.

The resolution having been put to the meeting in the usual way, was declared carried with one dissentient.

The CHAIRMAN said the next resolution was :—

"*That Mr. John Marks, of 113, Great Russell-street, W.C., Mr. J. M. Klenck, 42, Bishopsgate-street Within, E.C., and Mr. Louis Scaby, of 23, Churchfield-road, Ealing, be and they are hereby appointed liquidators for the purpose of such winding up.*"

Mr. HIRSCH formally moved the resolution, observing that he need make no remarks on the subject. They all knew those gentlemen thoroughly well, and he was sure they would do the very best they could for the interests of the Company. It was a matter of very great importance at this particular stage of their affairs that they should be elected unanimously.

Sir HENRY HOARE remarked that he had not one word to say against the reputation or business qualities of the gentlemen proposed because he did not know them; but he would be extremely glad to be told what the position of the Company was, and what those gentlemen had done for the Company, he not having been able to go to their offices for the last five years. Formerly he had been received by Mr. Watt with the greatest courtesy; but it seemed that that gentleman was not in very good odour with the meeting, and therefore, in common justice to Mr. Watt and to the gentlemen now proposed, he would like to hear briefly what was the

Digitized by Google

position of the Company and what were the allegations against Mr. Watt.

The CHAIRMAN, in reply, intimated that when they came to the next resolution he would be glad to supply the necessary information.

Mr. HODGE seconded the motion.

Sir HENRY HOARE said that he was desirous of getting the information before giving his vote in support of the election of the liquidators.

Mr. HIRSCH said that there was an easy answer to the last observation, namely, that if Sir Henry had attended the previous meetings he would have heard all that could be said in connection with the affairs of the Company and against Mr. Watt. The time of the meeting ought not to be taken up by giving such information.

Sir HENRY HOARE replied that he had come to the meeting for that information.

Mr. RAMSDEN agreed with Sir Henry Hoare that the information should be furnished now.

Mr. JOHN NEWTON said that, in answer to the question now put, he would like to ask what had Mr. Watt done for the Company. He had heard Mr. Watt boast of having paid dividends, but he (the speaker) could only say that those dividends misled him into taking shares at 5s. that were not worth 5d. Mr. Watt had had possession of the Company for some years, and when he left it there where no funds in the till and no business of any moment being done. Notwithstanding that Mr. Watt took his £1,200 a year, and in addition a commission on all business introduced by him to the Company. The speaker contended that no Director in the world could take a commission on work introduced by him unless it was under the authority of a special resolution carried by the shareholders. Mr. Newton next proceeded to descant on the personal qualifications for the office of liquidators of the three gentlemen included in the resolution. As a member of the Investigation Committee, he was thoroughly convinced that it was not possible to select a better man than Mr. John Marks, or one who would look after their interest with greater zeal or uprightness—that was his opinion of Mr. Marks; he was satisfied he was a sound and good man of business. As for Mr. Klenck, every one who knew him would agree in the opinion that if there were a keen man of business, that man was Mr. Klenck. With reference to Mr. Swaby, he had witnessed the persistent and plucky way in which he had denounced the balance-sheet and withstood the attacks made on him by Mr. Watt, and they wanted some one imbued with that feeling to look after the interests of shareholders.

A SHAREHOLDER expressed his dissatisfaction with the manner in which the Company's affairs had been managed in the past, and said he saw no reason why the new Board would manage them better than the old one, and therefore he also would like to ask what the new Directors had done for the Company and what they proposed to do.

The CHAIRMAN wished to be informed by the last speaker what the new Directors could do coming into a concern of that kind with a balance of £2. 16s. at their command, and writs of all kinds flying about their heads from creditors of the Company. The best thing that they could do was to go to the bank of the Company and ask for an overdraft of £1.000, but the bank would not give the money on the security of the Company, but on that of the individual Directors. Having got the money on their own security, the Directors found the writs so numerous that they could not pay everybody. They inquired into the justice of the claims, and found that in most cases they were just claims, and they did the best they could to meet them. They appointed a firm of chartered accountants to investigate the accounts. What did the latter find? That the balance-sheet which Mr. Watt issued to the shareholders was absolutely false. Mr. Watt showed a false profit of £1,550, and took 5 per cent. commission on the amount. Not only did he take 5 per cent. commission on that profit, but the actual sales which he had entered in the books as *bonâ fide* sales were found to be bogus sales entailing a serious loss on the Company. That was what Mr. Watt had done for the Company, and it was through his management, or rather mismanagement, that the Company stood now where it did. Mr. Watt had sent out a circular as the holder of 8,000 shares, in which he said he could not permit the Company going to ruin without an effort to prevent it. Mr. Watt really held 7,376 shares; but he had actually sold 6,500 of those shares, and as soon as the transfers came into the office the Directors refused to recognise them. They had a lien on those shares, and they asked for the sum of £4,600, which they alleged that Mr. Watt had abstracted from the Maxim-Weston Company.

The resolution was then put and carried with three dissentients.

The CHAIRMAN then said that in considering this reconstruction scheme they had to consider, in the first place, what had brought them to the unfortunate necessity of winding up the Company and reconstructing it. As he had already shadowed forth, they alleged that it was entirely due to the maladministration of Mr. Hugh Watt during the time that gentleman was Managing Director of the Company. The new Board on taking office found everything in the most disordered condition, with the large balance of £2 odd at the Consolidated Bank, while they were inundated with writs from agents and others who had not been paid their salaries for a considerable time, and who had probably been appointed by Mr. Watt, though in the opinion of the new Directors they were not necessary, and also from creditors for goods supplied, and so on. The Board did the best they could under the circumstances. As he had told the meeting, they borrowed money from the bank on their own personal security, and with that money satisfied the creditors as far as they could. As soon as Mr. Watt found that they could carry on the affairs of the Company without him, he started an action in the Court of Chancery for the compulsory winding up of the Company. They defended that petition, and successfully in this way, that the Court decided that, as there were matters of accounts between the two—that was to say, that as the Company had claims against Mr. Watt and Mr. Watt alleged he had claims against the Company—the petition should be dismissed, the two parties paying into the bank in the joint names of the respective solicitors to the Company and to Mr. Watt the sum of £500, to abide the result of the action that the Company commenced against Mr. Watt and the action that that gentleman brought against the Company. That had been done, the money being lodged in the London Joint Stock Bank. The Directors had to find that amount out of their own pockets, to keep things going until the shareholders should be called together, and to know whether they would take up the unissued shares that the Directors had asked them to take up, but which the shareholders would not take up. Each of the four members of the Board found £125 for the purpose named. The Chairman then proceeded to refer to a circular which he said was issued by Mr. Watt on the 2nd October, insinuating accusations of the gravest character against gentlemen of untainted reputation. He read *seriatim* the various charges made in the circular in question, and said that there was not a word of truth in any of them. Coming to the prospects of the Company, he remarked that, provided the scheme proposed was carried out, the shareholders would provide a capital of £15,600, which would be ample to continue the work of the Company. He regretted to say that only during the last month they had to let contracts slip by that would have brought in a clear net profit of £1,500, which would have been sufficient of itself to pay a dividend of 2½ per cent. If they could have done that in the last month, what might they not expect in the remaining eleven months? The prospects of the electric light were never so promising as at the present time, and he felt every confidence that, if the shareholders would only take up the proposed scheme, they would be able at the end of the year to come before them with a balance-sheet that would show a very fair dividend. He hoped the shareholders would show a united front to the world in passing the resolutions before the meeting. The Directors had endeavoured to make their project fall as lightly as possible on the shareholders by proposing that 3d. per share be paid on application, and 3d. on allotment, and the

balance, if required, at no earlier date than six months. He then read a letter he had received from a lady shareholder, in which she described the affairs of the Company as having been "infamously muddled." The Chairman said that he quite agreed with the remark, adding, "but not by the present Board." He concluded by moving the remaining resolutions, as follows :—

That the liquidators be and they are hereby authorised to sell and transfer, subject to due provision being made for dissentient shareho'ders (if any), all the letters patent, business, property, machinery, plant, assets and effects of the Company, whatsoever and wheresoever, to a company to be formed with limited liability, under the Companies Acts, 1862 to 1886, with a capital not exceeding £75,000 divided into 500,000 shares of three shillings each, for the purpose, amongst other things, of taking over and working the property of this Company upon the following terms :—(a.) *The new Company shall pay and discharge the debts and liabilities of this Company, and also the expenses of and incident to the winding up of the same, and of the incorporation of the new Company, and of the sale and transfer by the liquidators of the assets and liabilities of the Company to the new Company.* (b.) *The new Company shall allot and issue to the liquidators, or as they shall direct, 312,000 shares in the new Company of three shillings each, upon each of which there shall be credited the sum of two shillings, a proper agreement being filed with the Registrar of Joint Stock Companies before the issue of such shares, so that the same may be liable to the payment of one shilling per share and no more.*

That the liquidators be and they are hereby authorised and directed to procure to be allotted to every member of this Company requiring the same one share in the new Company, with two shillings credited as paid thereon, for and in respect of every share held by him in this Company ; provided always that, to entitle the members of this Company to an allotment of such new shares, application must be made for the same in writing within ten days after the posting of a notice informing him of his right to apply for the same, addressed to his registered address in the books of the Company. If no such application is received by the liquidators within the time limited as aforesaid, the right of such members to receive such proportion of shares shall be abso'utely at an end, and the liquidators, in order that the necessary capital may be promptly raised, and the liquidation closed, shall dispose of any shares refused or not applied for as aforesaid to any person or persons, whether shareholders or not, at such price (if any) and upon such terms as the liquidators may think fit.

That the liquidators be, and they are hereby authorised to continue the business of the Company pending the transfer thereof to the new Company, and to consent to the registration of the new Company by the same or a similar name to that of the Company.

Mr. KLENCK seconded the resolutions, and said that the scheme embraced therein was the only way out of their difficulties, and expressed his confidence in the success of the Company if it was carried out.

Mr. STEND supported the resolutions at considerable length, reviewing the history of the Company.

Sir HENRY HOARE thanked the Chairman for his extremely open, candid, and explicit statement, adding that he thought that the Company under the direction of the present Board would prosper, and that he would be happy to give them all the support he could.

Mr. ABRAHAMS (Solicitor to Mr. Hugh Watt) then addressed the meeting, and put a series of carefully framed questions to the Chairman bearing on the legal aspect of the proposed scheme, and on the *modus operandi* to be pursued. He also entered a mild protest against the Chairman's strictures on Mr. Watt in the absence of that gentleman.

In answer to Mr. SPICER,

The CHAIRMAN said their liabilities were as nearly as possible covered by their book debts, which they considered good debts. He then replied to Mr. Abrahams, remarking that the three Directors of the present would be the Directors of the new Company. It was specially provided in the Joint-Stock Companies Acts that the value of the shares of those who dissented from such a scheme was settled by arbitration. Whatever sum the arbitrators for the Company and the dissentients found to be the value of the shares would be paid to the dissentients. He did not feel alarmed that they would have a large list of dissentients, as Mr. Abrahams did. With regard to the expenses of the liquidation, if they wanted a grant for them the liquidators would come before the shareholders and let them fix the remuneration. With respect to Mr. Abrahams' remark that he (the speaker) was prejudging Mr. Watt while the action already referred to was *sub judice*, and that in the law of England a person was assumed to be innocent until he was found to be guilty, the speaker would remind Mr. Abrahams that the Solicitor-General (Sir Edward Clarke), in the case of Watt *v.* Cameron, said that Mr. Watt was an unblushing liar. Therefore he (the speaker) did not think that he had prejudiced Mr. Watt in any respect. The amount of liabilities ranged from £2,000 to £2,500, and they had book debts to that extent.

In further reply to Mr. JOHN NEWTON,

The CHAIRMAN said that the present Directors had not received a penny in the shape of fees or any other form, but, on the contrary, had found money at 5 per cent. to carry on the Company, whereas, when Mr. Watt managed it, and advanced money, he took 10 per cent. for it.

He then declared the whole of the resolutions to be carried by a three-fourths majority. A vote of thanks to the Chairman and Directors brought the proceedings to a close.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended November 30th, 1888, amounted to £5,600. The directors declare an interim dividend of 3s. per share, or at the rate of 6 per cent. per annum, free of income-tax, for the quarter ended September 30 last, and payable on the 24th inst. The books of this company will be closed from the 17th to the 22nd inst., both days inclusive.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during November was 4,013, estimated to produce £3,100, against 3,343 messages, producing £2,998 in the corresponding month of last year. The traffic receipts for August, estimated at £2,800, realised £2,860.

DIRECT SPANISH TELEGRAPH COMPANY.—The traffic receipts of this company for the month of November, 1888, amounted to £1,950, against £2,115 in the corresponding period last year.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this company for the month of November, 1888, amounted to £59,862, against £53,454 in the corresponding period last year.

EASTERN EXTENSION, AUSTRALASIA AND CHINA TELEGRAPH COMPANY.—The traffic receipts of this company for the month of November, 1888, amounted to £45,234, against £39,000 in the corresponding period last year.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic receipts for November, 1888, amounted to £24,000, and for the period from 1st January to 30th November, 1888, to £250,200. For the corresponding months of 1886 and 1887 they amounted to £239,000 and £242,880 respectively.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended November 30th, 1888 (after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, Limited), were £4,672.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—The traffic receipts of this company for the month ended 30th November, 1888, amounted to £5,975.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The traffic receipts for the half-month ended November 30th, 1888, were £2,889, as compared with £2,689 in the corresponding period of 1887. The August receipts, estimated at £5,002, realised £5,149.

APPOINTMENTS.—The Board of the Direct United States Cable Company (Limited) have appointed Mr. Tavenor Finnis to be secretary and accountant, and Mr. P. Oscar L. Moll to be traffic manager of the company.

NEW VALVE

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 552.—Vol. XXII. FRIDAY, DECEMBER 14, 1888. Price 4d.

NOTES.

Amongst our correspondence will be found an important letter from the laboratory of Prof. Rowland, from which it will be gathered that preparations are being made for a repetition of the classical experiment on the magnetic effect of convection currents. It will be remembered that Dr. Lecher recently failed in an attempted verification of this experiment, but the actual existence of the effect seems already to have been placed beyond dispute.

We print elsewhere the programme which has been drawn up by the "Preparatory Committee" of the International Congress of Electricians, which is to be held in Paris in connection with the forthcoming Exhibition. The meetings of the Congress will be open to all electricians on the payment of a subscription of 20 francs, and each member will receive a copy of the *Transactions*. The exact date has not yet been settled, but it is understood that it will not be earlier than August 15th. This seems unfortunate, since it will then be inconveniently near, even if it does not clash, with the meeting of the British Association. The Committee is to consist of 100 members, of whom 25 will be French and 75 from other countries. We understand that the invitations will shortly be issued, but the list of names will not appear pending their actual acceptance. We fear that the programme which has been drawn up will not greatly commend itself to the English electricians, but upon that subject we have written at some length in another part of this issue.

Contemporaneously with the alteration of the title of the quondam Society of Telegraph-Engineers and the election of the foremost living Electrician to the Presidential chair, other efforts are to be put forth to raise the general tone of the Institution. This movement, if judiciously directed, must command the sympathy and, indeed, the active co-operation of every electrician who takes a proper pride in his profession. The Institution is undoubtedly fortunate in the possession of a conspicuously successful illustration of what such a society should be in the Institution of Civil Engineers, to whose generous hospitality it is so much indebted. In the dignity and gravity of its proceedings, and in the better organisation of its debates, much benefit would incontestably accrue if the example of the Institute of Civil Engineers were more closely followed. So long, however, as the terms of admission to the membership of these institutions remain on radically different bases, it is manifestly impossible for the younger organisation to emulate the position and status of the elder; but the time has not come as yet for a reconsideration of this fundamental question.

We also understand that, as a step in the direction indicated, and with a view of increasing the importance of the *Journal*, and also as a means of obviating a certain amount of that "playing to the gallery" of which some members are rightly or wrongly accused, a section at least of the Council is in favour of following the practice of the Civil Engineers in the exclusion of reporters from its debates. This is a question upon which much might obviously be said on either side. It might plausibly be argued, for instance, that the presence of reporters has a restraining tendency rather than the reverse. Nor do we feel satisfied that the particular evil complained of exists to so serious an extent as is sometimes alleged. It is not our intention, however, to argue the *pros* and *cons* of the matter, which we shall be content to leave to the united wisdom of the Council. But it is much to be desired that whatever decision may be arrived at will be one that will commend itself to the general body of members, and not merely the result of a bare majority upon the Council itself.

The hearing of the appeal in the case of Ferranti *versus* Gaulard-Gibbs is now fixed for the commencement of Hilary Term, when it will be the first appeal case on the lists.—The arguments in the appeal of Edison-Swan *versus* Holland and others were concluded yesterday (Thursday) evening; judgment being reserved.—The hearing of the evidence in the compound-winding action at the Edinburgh Court of Sessions was concluded on Friday last, but the evidence of Mr. Brush and other American witnesses has still to be taken on commission. Judgment will not, therefore, be delivered until somewhere about the middle of January.

In this action it is part of the defender's case to show that in Varley's specification the words in which the winding and excitation of the field-magnets are described are of an ambiguous character. Of course we do not at present express any opinion whatever upon this point, but it led to a very funny scene in Court. To Professor S. P. Thompson was entrusted the delicate and difficult task of leading the Court to perceive how many separate and distinct inter-

Digitized by Google

pretations might be put upon the words "part of the electricity developed by the machine is diverted to maintain the magnetism of the soft-iron magnets." After the Court had been duly instructed as to the distinction between electric energy and electric current it became necessary to analyse the meaning of the word "divert." This proved a great source of obfuscation, until at length the "principle of bifurcation" was invoked to make all things clear. "Can you suggest," said the cross-examining counsel, "any operation to which the word 'divert' is so appropriate as the operation of bifurcation?" But Prof. S. P. THOMPSON promptly suggested several, so that for the time being things looked just as mixed as ever. A little later on Lord TRAYNER hazarded the surmise that "bifurcation is the production of a current at a certain point." Prof. THOMPSON said "Yes" to this, and then everyone felt better.

IF EDISON held no other claim to immortality—and *some* people believe that he is astonishingly well provided in this respect—he still, we think, deserves all the credit which has ever been awarded him for his invention of the definition-defying term "filament." The highest available forensic, judicial, and scientific skill of this age and country have been brought to bear upon the question, and that not once only but over and over again, and still, as LORD JUSTICE COTTON plaintively remarked this week, we seem to be no nearer knowing what a filament really is. His Lordship inclines to think that it must be something which "is formed before carbonisation;" but this only serves to show how far a reconciliation of legal subtilties and technical obscurities may remove the final issue from the category in which he who runs may read. For if this be indeed the definition of a filament, then our admiration for the inventor of the term will be more than ever profound.

IN connection with the Blackpool Tramway, which, as we recently noted, has now become a most successful commercial concern, our attention has been drawn to the fact that sufficient credit has scarcely been given to the firm of ELWELL-PARKER, to whose co-operation the present success is very largely due. Mr. PARKER's advice and assistance was sought by the directors at a comparatively early stage in the history of the affair, when there were still some serious difficulties to be surmounted. Since this promises to be in some sense an historical undertaking, it is additionally desirable that the credit should be fairly divided, and Mr. HOLROYD-SMITH, we are sure, would be the last person to think otherwise.

WE are very pleased to learn that the tender of Messrs. NICHOLSON AND JENNINGS for the lighting of Cowpen has at length been accepted. The agreement seems to be a fair and honest one on both sides, and it is at least evident that the contractors are not attempting to use this installation merely as a stalking-horse or an advertising boom, as has, unhappily, so often been the case in the history of electric lighting. The terms are 18 arcs for £575 per annum. We look forward to a genuine success at Cowpen, which will do something towards wiping out the disgrace of Barnet.

As to Barnet—what can be said, except that nothing could be more unfortunate for everybody concerned? What makes it all the more annoying is that, in reality, it is such a *very* simple matter to keep a few dozen lamps burning—if only proper engineering skill be exercised in planning and erecting the installation. Of course, if the rumour be true that the mains were cut on Saturday last by some malicious person or persons, this latest incident does not reflect any personal discredit upon the contractor, but it is most devoutly to be hoped in such a case that the miscreants will promptly be brought to justice. The other rumour, to the effect that Mr. JOEL selected Saturday evening as the most appropriate occasion for making some changes in the machinery, may probably be dismissed as hypothetical. But no explanation, however exculpatory, can do away with the mischief created by the fact that, as all the world now knows, the electric light has again signalised its unreliability—at Barnet.

DUBLIN is not only a badly but an expensively-lighted city, and it is natural that strong efforts are being made there to introduce the electric light in the main thoroughfares and principal places of business. The price of gas in the Irish metropolis is abnormally high, and there should be no great difficulty in providing electrical illumination at a charge which would compare favourably with that now levied by the local gas company. Nevertheless, among the members of the Corporation of Dublin, as elsewhere, there are some who take a lively and apparently not altogether unselfish interest in the supremacy of the gas-works. Consequently a good deal of very unseemly wrangling, to say nothing of unparliamentary language, characterised a recent meeting of the Corporation to discuss the question of raising the necessary funds to lay down the plant for electric lighting. In the end the proposition appears to have been defeated for the time being by the casting vote of the chairman. This close voting, coupled with the circumstances referred to above, induce us to think that the subject has not been finally disposed of, and that before another winter the city of Dublin will be permitted to test the merits of the light of which it stands so much in need.

WE understand that the machines at present in use at the Whitehall Central Lighting Station are to be replaced by Siemens dynamos, and the present batteries by Elwell-Parker cells. As this change is not unlikely to lead to legal proceedings, more will doubtless be heard of this anon.

FROM a French source we learn that some of the Roman Catholic citizens of the United States are anxious to avail themselves of the privilege of the confessional by means of the telephone, and that the subject is now occupying the serious attention of the Church. It has already been reported that the United States Courts have allowed an offender to plead guilty by telephone—if we recollect aright he was fined five dollars. But, considering the attitude which the Roman Catholic Church has hitherto studiously observed towards scientific progress, it will be strange indeed if the telephone becomes an adjunct to the confessional—even in the United States.

UNDER the attractive title of "Electric Lamps from Cabbage Leaves," a provincial journal has been made the victim of one of the most delicious skits which we ever remember to have come across. The article is too long for quotation in this place, but will be found at the end of the "Notes."

Melbourne Exhibition Awards.—We are glad to learn that Messrs. Ransomes, Sims and Jefferies (Limited), of Ipswich, have just been awarded a gold medal for their steam engines at the Melbourne Centennial Exhibition.

The Electric Light on the New Pullman Train to Brighton.—The new "Pullman Vestibule Train" now running between London and Brighton is profusely supplied with the electric light. The dynamo is carried in the brake van, with the 32 E.P.S. accumulators, which are capable of affording a 10 hours' supply. The dynamo is geared on to the axle of the brake van in the well-known manner designed by Messrs. Stroudley and Houghton.

The Ipswich Central Station.—The central station at Ipswich, which has been carried out by Messrs. Lawrence, Paris and Scott, commenced last week to supply current to the offices of the *East Anglian Daily Times*, and as soon as other machines are in place the lighting will be extended to the premises of other private consumers. The engines have been supplied by Messrs. Ransomes, Sims and Jefferies.

St. Pancras Vestry.—At the last meeting of this vestry a notice was read from the Metropolitan Electric Supply Company, notifying their intention to apply for powers to light Hampstead, St. Pancras, and Islington with electricity. A similar notice was received from the London Electric Supply Corporation in reference to lighting with electricity the whole or greater part of the metropolis. A letter was read from the House-to-House Electric Light Company on the same subject with reference to St. Pancras.

"Calvert's Mechanics' Almanack."—The sixteenth number of "Calvert's Mechanics' Almanack" is as replete as ever with tables, formulæ and information of all sorts. We notice a clear and concise summary of the Patent Law Amendment Bill, and amongst other useful items some carefully compiled hydraulic memoranda, a table of the tensile strength of manganese steel bars, and an interesting note upon the action of oils on metal. This little publication ought to prove of great use to all engaged in mechanical and kindred operations.

A Curious Effect of a Lightning Stroke.—A correspondent writes us from Paisley as follows:—A curious effect of a lightning stroke was observed a fortnight ago at some bleach works five miles from this town. A chimney attached to the works was struck by lightning, and about 20ft. of the top destroyed. The lightning conductor was earthed in a pond which supplies the works with water, and after the flash it was noticed that a great many little fish (minnows) floated to the surface dead, evidently having been killed by the discharge.

The Paris Exhibition.—It has been declared by an Order in Council that the conditions of the Patent Act, 1883, under which an application for a patent is not to be invalidated by the exhibition of an invention at an International Exhibition, are to apply to the Paris Universal Exhibition, and also that exhibitors are to be relieved from the conditions of the above Act, under which they were required to give notice to the Comptroller of Patents of their intention to exhibit the article afterwards sought to be patented. The regulations also apply to designs intended to be registered.

The Pall-mall Central Station.—At the last meeting of the St. James's Vestry Mr. Keevil called attention to a huge smoke shaft which is being erected not far from Marlborough House, for the purposes of the Pall-mall Electric Lighting Company. He said that he feared that the vestry did not realise the importance of the proceeding when a majority gave the concession for the erection of a shaft in such a central position. He moved that the whole question be deferred until the new County Council had an opportunity of considering the subject. The motion was lost, and Mr. Keevil then said that he would convene a meeting of the ratepayers for the purpose of calling attention to the matter.

American Storage Batteries.—We learn that the Woodward Electrical Company, of Detroit, have arranged to supply the Detroit battery to the English market. Messrs. Shippey Brothers (Limited) have been appointed sole agents for the United Kingdom, pending the establishment of works in England, to manufacture the Woodward plate for the European markets. We understand that the patents of the Woodward battery are held by a very powerful group of American capitalists, who have recently extended the works, in order to turn out 500 cells per day. Messrs. Shippey Brothers will shortly have on view a complete range of batteries, in all sizes, for lighting, traction, and medical purposes.

Reckenzaun's Tramcars in the United States.—In our "American Notes" of November 9th it was stated that Mr. Barr, the president of the Lombard and South-streets lines in Philadelphia, expressed his entire satisfaction with the performance of Reckenzaun's car, which had then been running for many months in ordinary daily service. Advices have now been received of the successful introduction of the same system in the City of Sacramento, California. The inauguration took place on the 20th ult., on the lines of the Central-street Railway, four miles long, which has been especially built for electric traction, with accumulators. These cars are similar in design to the one we describe this week in another column, and which has been made for a tramway in Australia.

Acceptance of a Tender for the Lighting of Cowpen.—On Wednesday, the 5th inst., an informal meeting of a committee composed of all the members of the Cowpen Local Board was held to consider the advisability of lighting the town with electricity. The chairman (Mr. Robinson) said he had called the meeting for the purpose of hearing an explanation from Mr. Nicholson, of Messrs. Jennings and Nicholson, electrical engineers, of London. After the explanation and conference, a memorandum of agreement was drawn up and initialed by the chairman on behalf of the Board, and by Mr. Nicholson on behalf of his firm, for lighting the township by electricity. On Friday, at a special meeting of the Local Board, it was unanimously decided that the tender of Messrs. Jennings and Nicholson, to light Cowpen township with 18 arc lights for £575 per annum, with option to purchase the plant during the five years' term, be accepted. The township has been in darkness since August, so that considerable satisfaction is expressed with the decision of the Board.

The Smithfield Show.—Messrs. Robey and Co. are exhibiting several of their well-known engines at the Smithfield Show. Amongst others a ten horse-power (nominal) horizontal steam engine fitted with their trip-expansion gear and their electric regulators, by means of which the engine adapts its speed to the number of lamps burning, and can also adapt itself to the work of charging accumulators. Messrs. Robey and Co. also show a six horse-power vertical engine, an eight horse-power portable engine, and an eight horse-power horizontal engine. Amongst several exhibits of interest to agriculturists, Messrs. John Fowler and Co., of Leeds, show a useful-looking compound semi-portable engine, intended for electric lighting work, in which special attention has been paid to the maintenance of a constant speed under wide variations of load. Samples of Tatham's lead-covered cables and wires are also shown by this firm. Great care has been taken to secure high insulation for the electric light leads, low capacity for the telegraph wires, and a minimum of induction in the case of the telephone cables.

Telegraphy to the Continent.—On Monday last, in answer to Sir G. Campbell, Mr. Raikes stated that when the Post Office undertakes the working of the cables to the Continent the charge per word to Belgium will not at first be altered, but the charge to France, which is now 2½d., will be reduced to 2d. No particular proportion of the charge has been assigned to the cable transit. He was not in a position to give any information

Digitized by Google

as to the acquisition of the plant of the Submarine Telegraph Company, as no agreement on the subject had been arrived at. No pains will be spared by the department to ascertain the necessary cost of services such as this. Notice has since been given of several questions indicative of apprehension that the acquisition of the Submarine Telegraph Company's cables will be made at a price that will render necessary excessive rates for messages when the cable comes under the charge of the Post Office. It will be remembered that the terms of the company's charter, now about to lapse, do not include any provision for compensation. The cable and working plant will be taken over at a valuation.

Exports of Telegraph Wire, &c.—Our exports of telegraphic materials are generally small in November. The value of last month's exports, though larger than in the corresponding months of the two previous years, have virtually done nothing to redeem the unsatisfactory aggregate of this year's shipments, compared with previous years. The trade returns issued a few days ago enable us to give the shipments for the month, and the aggregate to November 30th, of telegraphic wires and apparatus connected therewith :—

The Proposed Pacific Cable.—We take the following editorial from the *Daily News* of December 11th :—"At the Congress of representatives of the Australian Chambers of Commerce, held on November 1, 1888, in Melbourne, a Paper upon the proposed new Pacific cable *viâ* British North America was read by Captain F. C. Rowan, who thought a second cable was necessary for mechanical, commercial, and political reasons. In such an ocean as the Pacific there is great danger of a single cable being broken or destroyed, which renders a duplicate cable almost imperatively necessary. Secondly, the saving to England and the Colonies by a consequent reduction of the tariff would be in the course of ten years over five million pounds; and, thirdly, it would more firmly unite the whole of Australasia with the Mother Country." Such are the chief points of Captain Rowan's address; but in speaking as if the cable were already laid, he does not appear to make much of the extreme difficulties of the enterprise —difficulties that are at once apparent when the immense depth of the Pacific Ocean and the liability to breakage on the coral reefs are taken into consideration.

The Counter-E.M.F. of the Arc.—The *Centralblatt für Electrotechnik*, No. 28, has a paper by Herr Hans Dubs, on a simple experiment relating to the above. Realising that in the arc itself there are so many other complicated phenomena present that renders the results obtained uncertain, he took a more simple case. Two pieces of carbon (both broken off the same plate) were placed with their edges rather less than a millimeter apart, and a benzine blowpipe jet turned on blowing from one to the other across the opening. On joining the two plates through a galvanoscope a deflection was obtained, the current always flowing the reverse way to the jet, *i.e.*, if the jet blew from plate *a* to plate *b*, the current was from *b* to *a* and *vice versâ*. A stronger current was obtained by heating a part of one carbon in a hydrogen blowpipe and bringing it in contact with the other, the current flowing from the cold to the hot. The same experiment with copper gave a less effect, and with iron hardly any. He mentions that the electric furnace at the Neuhausen Works, which takes a current of some 12,000 amperes, gives a considerable return current for some time after the main current has been cut off. Herr Dubs hopes shortly to repeat his experiments with a more powerful blast and to make some electrometer measurements.

The Society of Telegraph-Engineers and Electricians.—A special general meeting of members of the Society of Telegraph-Engineers and Electricians will be held at the offices of the Society, No. 4, The Sanctuary, in the City of Westminster, on Thursday, the 20th day of December instant, at 5 o'clock p.m., when the resolutions respecting the change in the title which were passed at the special general meeting of members on the 22nd November, 1881, will be submitted for confirmation as special resolutions pursuant to Section 51 of the Companies Act of 1862. This meeting is rendered necessary owing to the discovery that the previous meeting was informal, a period of fourteen clear days from the passing of the resolutions as required by the Act not having transpired. At the same meeting the following further resolution will be proposed, and if passed by the required majority, it will be submitted for confirmation as a special resolution to a further special general meeting of members, which will be held at the Institution of Civil Engineers on Thursday, the 10th day of January, 1889, at a quarter before eight o'clock in the evening :—Resolution : "That the Regulations of the Society of Telegraph-Engineers and Electricians, as contained in their Memorandum and Articles of Association, be altered by substituting the name 'The Institution of Electrical Engineers' for 'The Society of Telegraph-Engineers and Electricians,' and also by substituting the word "Institution" for the word 'Society' wherever the same respectively occurs in the regulations."

Barnet in Darkness.—We take the following from the *Daily Chronicle* of December 10th :—"Saturday night was the third occasion, since the adoption of the electric light, on which the town of Barnet has been plunged into darkness by reason of some mishap or defect in the arrangements for public lighting. On this occasion the electric light was brilliant from dusk to about half-past seven, when it suddenly went out. The occurrence was particularly unfortunate as the streets were very busy at the time, and numbers of persons resident in the town and in the surrounding villages were engaged in shopping. A thick fog prevailed, and for some time pedestrians were literally groping their way. The police were on the alert, but some few tradesmen complain of the loss of certain of the wares which were exposed for sale outside their shops. It was alleged that a wire had been maliciously cut, and the circuit so broken, and further that a workman recently discharged by the contractor was suspected of the outrage. A more probable explanation, however, is to be found in a letter which the contractor recently addressed to the local board, informing them that he was about to make a change from temporary to permanent engines and plant, and asking to be excused if, in the transition state, any hitch should occur. Whatever the cause may have been, the light was not again available for nearly two hours. At a previous meeting of the Barnet Local Board Mr. Yolland attended, and complained that for three nights one of the lights in Park-road had not been alight. The Chairman (Mr. C. Stevens) stated that the Board "are spending a great deal of time on the subject of the lighting of the town." This, however, did not satisfy the complainant; and he asked that an oil light should be placed in the gas lamp, to which the Chairman replied : "We must not do that; but we are seriously considering the matter." A letter was then read from the Board of Trade informing the Board that it would be necessary for Mr. Joel to acquire statutory powers for lighting the district of the Board with electricity; and the Clerk was instructed to inform the Board of Trade that, under his contract with the Board, Mr. Joel had to do so at his own expense if it was required. The Board subsequently went into committee for the consideration of the subject of electric lighting, and, after lengthened discussion *in camera*, instructed the Clerk to give notice to Mr. Joel to remedy the defects in the lighting within fourteen days.

Leamington.—At the recent monthly meeting of the Leamington Corporation, a discussion took place respecting the lighting of the Parade with electricity, by the Midland Electric Light and Power Company. Some time ago the company erected four arc lamps outside the town hall and several "sunbeams" in other parts of the town, in order to give the Council an opportunity of saying which system they preferred.

Digitized by Google

The question now arose on a report by the Watch Committee, who recommended that a decision should be at once arrived at respecting the three alternative systems, and calling upon the company to state forthwith the cost of supplying each system, as well as all charges for maintenance.—Alderman Wackrill, in moving the adoption of the report, urged that sufficient time had been allowed to enable the Council to form a judgment as to the relative merits of the three systems.—Alderman Gilbert seconded the proposition, and said that the company had been playing with the town.—Mr. Davies repudiated the notion that the Council had unfairly criticised Messrs. Chamberlain and Hookham, or had in any way cast reflections on their ability as electrical engineers. Those gentlemen had promised to give the best possible exhibition of the arc system, but the result had been unvariably unsatisfactory, one arc light being always bad, frequently two were defective, sometimes three, and occasionally the fourth. The "sunbeam" system furnished a beautiful light, but as it involved an outlay of £600 a year its adoption was practically out of the question. The fifty candle-power lamps in Bath-street would entail a still greater permanent charge. On Sunday night anyone who saw in the soiled glass globes on the Parade and the red firefly which they contained would be out of his senses to imagine that such a light would attract people to Leamington. The light would not attract a moth. In his opinion the cost of lighting the Parade efficiently by electricity would be so great that the game would not be worth the candle.—Mr. Fell complained of the dirty condition of the lamps, and said that many of them were only giving six candle-power light instead of sixteen.—Dr. Thursfield called attention to the increased cost of maintenance of the "sunbeam" burner, the life of which was, he said, comparatively short, while the light became dimmer the longer it was burning.—Mr. Barter-White hoped that care would be taken not to exceed the term —which expires on Thursday next—during which the experiments were to be continued without prejudice to the existing contract.—The report of the Watch Committee was unanimously adopted, and it was agreed that a meeting of the General Purposes Committee should be held at an early date for the purpose of discussing the question, after the electric-lighting company shall have submitted the cost of the several systems now before the town.

The Swinburne Incandescent Lamp.—In the *East Anglian Daily Times* of Friday, December 7th, the following letter appeared as an article in the front page, and was evidently inserted in the most perfect good faith :—

"A NEW INDUSTRY AT CHELMSFORD."

"ELECTRIC LAMPS FROM CABBAGE LEAVES."

"Mr. Vandeleur, of Moulsham, writes :—I think your readers may possibly be interested to hear something about the new process for making incandescent or 'glow lamps' for electric lighting, which has been worked out by Messrs. Swinburne, and which, if commercially successful, will be an entirely new industry for Chelmsford. Briefly the process is as follows, certain essential details, however, which the inventors prefer to keep secret for the present, being of course omitted. The essential novelty of the process consists in employing vegetable fibre for the 'filament' or thread. Almost any plant leaf will do, but after experiment it has been found that the leaf of the common cabbage answers the purpose best, as it is tough and fairly homogeneous in structure. Each leaf is first separately examined by polarised light to detect any flaws or holes, the smallest pin-hole rendering the leaf practically useless. It is then soaked in vinegar for twenty-four hours in order to neutralise the alkali in the fibre, and after thorough washing is ready for the next process. It is now laid out flat in a solution of mercury bromide ; a rod of specially-prepared shellac is then taken, and after being raised to a high potential condition by treatment with a silk exciter, it is put into contact with the mercury solution. By this means the leaf is gradually electrolysed, the potassium and sodium in the fibre combining with the mercury to form a coating of amalgam. In this state the leaf is a capital conductor, and the inventors have even succeeded in using it as a substitute for lead in secondary batteries. A heavy current is now passed through it so as to carbonise the vegetable fibre, the current being increased till every trace of amalgam is volatilised. It is then cut into filaments, and each is forced through a draw plate of polished chlorine. As it is not of sufficient "resistance," resort has to be had to a process called "flashing." This consists in passing a mixture of neumonia and hydrogen gases over it while it is heated by the electric current. The scaly brown incrustation of carbon monoxide is reduced by the pluroneumonic acid formed (the exact reaction is not known, but is something of this kind—HN3+OC2+J=JO2+H5). The resistance rapidly rises, and at the proper point the current is automatically cut off by an ingenious switch arrangement. The filament is now bent into horse-shoe form and is ready to seal into the bulb. Perhaps the most important discovery made by Messrs. Swinburne is the enormous increase in light that can be obtained for a given current by employing an atmosphere of slightly compressed oxygen in place of the complete vacuum hitherto customary ; and though by this means the life of the lamp may be slightly shortened, it is not considered important in view of the great gain in light. If this process, beautifully simple as a laboratory experiment, should prove commercially successful, large quantities of picked and selected leaf will be required, and Messrs. Swinburne contemplate inviting tenders from some of the leading growers in the county. The bulk of the plant has been already erected, and Messrs. Crompton and Co., of Chelmsford, who are working overtime, have got the machinery well in hand, and hope to complete delivery by the 24th inst."

The Proposed Electric Lighting of Dublin.—At a special meeting of the City Council of Dublin on last Wednesday week the question of the electric lighting of the city was discussed on the estimate of the Finance and Leases Committee coming up for confirmation.—The High Sheriff (Mr. J. Winstanley), in moving the adoption of the estimate of the Finance and Leases Committee, said that the figures were rather alarming, being £6,795, as against £3,651, an increase of £3,144. The adoption of the electric light would alone cause about £2,300 of this additional expense.—Mr. Shanks pointed out that there was an estimate for £804 to meet expenses in connection with a loan for £6,000 for electric lighting purposes. He was not aware the Council had sanctioned such a loan.—The Town Clerk replied that the Council had authorised the obtaining of a license, and necessary expenses in connection with it.—Mr. Dawson moved a reduction of the amount of the estimate by £1,404, made up as follows :—£804. 15s. expenses in connection with the electric lighting loan ; £500 for maintenance ; and £99 less cost of collection.—Mr. Gill said he believed the corporation were going into a thing which would entail an enormous expense on the community. People might say : "Oh, you are a gas shareholder, and have no right to speak on this matter." Notwithstanding that he was a shareholder in the gas company, he considered himself, as a member of the Council, bound to protest against the enormous expense that was going to be put on the city. The Corporation were rushing into an enterprise the end of which no one saw, and which would saddle the citizens with probably £25,000 of expense. He believed the gas company were also going in for electric lighting ; but they had some reason of their own. It was not for any profit they would make through it, because he believed both the gas company and the Corporation would incur heavy loss. He might point out that in parts of America where electricity was successful, it competed with gas at from 12s. to 15s. per 1,000 cubic feet, instead of 3s.—Mr. Doyle said it struck him as an anomaly that Mr. Gill, who was a large shareholder of the gas company, should oppose this motion, when the gas company themselves were about to apply for a Provisional Order for the purpose of enabling them to furnish electric light. His reason for voting for the experiment was that he thought the monopoly of lighting should not be altogether in the hands of the gas company.—The High Sheriff intimated that he would assent to the reduction of the estimate by £1,400. It would stop the loan for a year. On a division being taken on the amendment the voting was equal.—The chairman, believing that it was the wisest course for the Council not to press for the money, said he would give his casting vote for the amendment.—Mr. Robertson moved a further amendment :—"That the estimate be reduced by £402. 7s. 6d. (instead of £804. 15s.) to meet the expenses of a loan for the expenses of electric lighting."—Alderman Byrne, in seconding the amendment, said the committee could not get the work done for them by a small contractor if the money was not forthcoming for a year. Only a large contractor, who would charge more, could wait out of his money for a year.—After a prolonged discussion a division was taken ; and the numbers being again equal, the chairman gave his casting vote against the amendment ; and Mr. Dawson's amendment, reducing the committee's estimate to £5,200, was adopted

NOTES ON ELECTRO-MAGNETIC INDUCTION.

BY DR. J. A. FLEMING, M.A.

(Continued from page 101.)

Comparison of Theory and Experiment.—Masson and Breguet carried out a series of experiments on induced currents. The principal part of their apparatus was a commutator keyed on a revolving shaft, which enabled them to separate the direct and inverse-induced currents. Two brass wheels were keyed on one shaft, but insulated from it, and the wheels had depressions cut in their periphery which were filled up with ivory. These wheels could be shifted relatively to each other, and were insulated from each other and from the shaft (*see* Fig. 12). Two springs pressed against the edge of the wheels, and two against the hub of the wheel. The whole arrangement served as a means to break and make one circuit, and at the same time to control a second circuit so that it was broken at the time when the first was made, and made at the time when the first was broken, or *vice versâ*. One of these wheels was inserted in the circuit of a primary coil and battery, and the other in the circuit of a secondary coil and galvanometer. On rotating the wheel at a certain fixed speed the series of "break" and "make" induced currents are separated out; all one set are stopped out and all the other are sent through the galvanometer. In this way it was shown that the quantities of the induced currents were equal, but very different in maximum magnitude, and hence in duration, the break-induced currents being greatly superior in making sparks.

Lenz* wound a spiral of wire on the soft iron armature of a magnet and connected the ends of the wire to a ballistic galvanometer. He detached the armature suddenly, and ob-

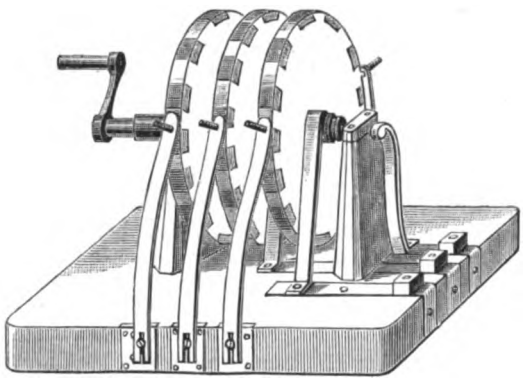

FIG. 12.

served the throw of the galvanometer. If θ denotes the angle of deflection and x the number of windings, he found that the product $\frac{1}{x}\sin\frac{\theta}{2}$ was a constant quantity, which shows that, *ceteris paribus*, the quantity of electricity set in motion was in proportion to the number of lines of induction withdrawn from the circuit. He also established experimentally, in confirmation of Faraday, that the electromotive force of induction was independent of the width, thickness or material of the wire windings,† and by other experimentalists also the fact has been established that the electromotive force is independent of everything except the form of the conductor and the nature of the change it experiences in relation to the magnetic induction through it. Felici‡ carried out an extensive series of experiments on induction, using a form of induction balance.

In this apparatus a secondary circuit, consisting of two coils, is arranged in series with a galvanometer. These coils are so far apart as not to influence one another. In contiguity to each secondary coil is a primary coil, and the primaries are wound in opposite directions. The primaries are in circuit with a battery and a key. The circuits can be so arranged, by adjusting the distances of the coils, that the induction of the primaries on their respective secondaries balance each other, and the galvanometer indicates no current, however strong may be the primary current. If three pairs of coils (*see* Fig. 13) are thus taken and balanced, two and two, so that the induction of A on *a* is equal to that of B on *b* and C on *c*, then, if we connect the primary A in series with B and C in parallel, so that the current divides between them in the ratio of their resistances, and connect the secondaries with a galvanometer, all in series, so that the current in *a* is opposed to that in *b* and in *c*, then no induced current is detected when the battery circuit is made and broken. This proves that the quantity of the induction current is proportional to the strength of the primary current.

If a primary and secondary coil are taken in fixed positions and the "throw" of a galvanometer observed when a definite

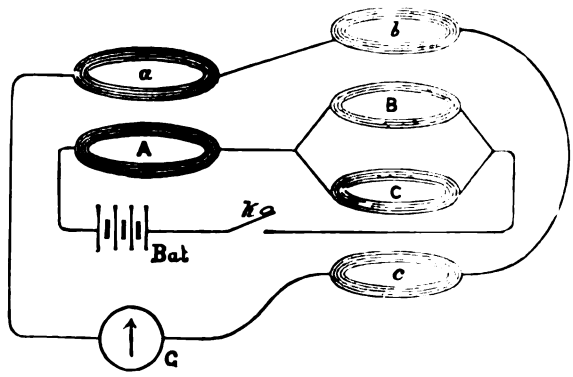

FIG. 13.

steady electromotive force E is applied to the primary, then if the position of battery and galvanometer are reversed, the application of the same electromotive force E to the secondary will give the same "throw" on the galvanometer now attached to the primary circuit, provided that the galvanometer and battery either have equal internal resistance or that their resistance is negligible in comparison with that of the coils. Hence we may assert that the induction of a circuit A upon B is the same as that of B upon A. For, if the resistances are R and S

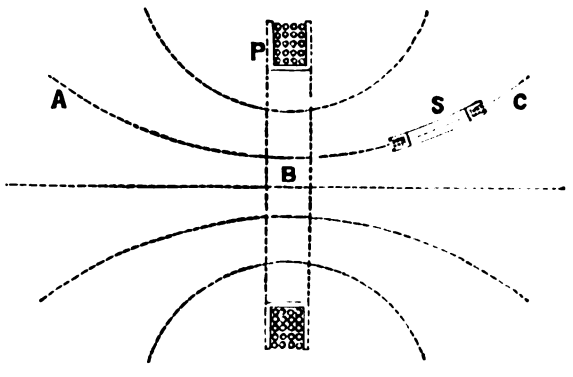

FIG. 14.

then we have seen that the total quantity Q of the secondary current is $\frac{M\,I}{S}$, when I is the steady value of the primary and M is the mutual inductance; but $I=\frac{E}{R}$, hence $Q=\frac{M\,E}{S\,R}$. If, then, the positions of battery and galvanometer are reversed, we get a quantity of induced current equal to $\frac{M\,E}{R\,S}$, which is the same as before. For any two coils it is possible to find a number of relative positions in which the interruption of a current in one produces no induced current in the other. In such cases the coils are said to be *conjugate* to each other. It is manifest that when in these positions the lines of induction produced by one coil do not pass through the other. It is possible to use one coil in this way to explore the field of another.

Digitized by Google

Let P be a primary coil and S be a small flat secondary coil, both being shown in section in Fig. 14. Then, if S is placed in a position conjugate to P, it will be found possible to move the coil S along a certain line A B C, maintaining the flat face of the coil always tangent to that line and so that in all these positions P and S are conjugate. It is evident that such a line is a line of induction of the coil P.

When one coil is in a conjugate position to the another, as far as regards inductive action they may be considered to be at an infinite distance apart. It follows, therefore, that if a coil is moved suddenly from a conjugate position to one not conjugate in the field of a primary traversed by a steady current, and then the primary current stopped at the instant of arriving at the second position, a galvanometer in the second circuit will have its needle jerked from one position of rest to another of rest, because the interruption of the current takes out of the circuit of the second coil just as many lines of induction due to the first coil as the motion from one position to the other put in.

(To be continued.)

LIGHTNING CONDUCTORS.—V.

BY DR. OLIVER LODGE.

(Continued from page 129.)

Application of Theory to the Last Recorded Experiments.

32. The agreement between theory and observation turned out so remarkably good in the last article that it encourages one to go into the matter a little further; for, although some of the precise numerical agreement is no doubt accidental, the numbers being easily changed one or two per cent. either way by differences in calculation, yet the discrepancies are well within errors of experiment, and their smallness seems distinctly to show that we are on the right tack, and have hold of the clue to a thorough understanding of these experiments.

But, concerning the value of μ, I was in considerable uncertainty, and chose two very different values merely to see how the results would come out. That they came out so very comparable with experiment was a matter of surprise to me, and was not expected till quite the end of the calculation, when I found it necessary to make the observations detailed in § 21 in order to interpret the spark-length indications.

In order to gain some information as to what value of μ was probable for the case under consideration, I wrote to our authority in magnetism, Prof. Ewing, asking him what value of μ was probable for an iron wire conveying a rapidly alternating current; and have just obtained from him a reply, which, being of general interest, I quote :—

"Next to nothing is known, I believe, about the value of μ for rapidly-alternating magnetic force. There is certainly a true magnetic viscosity; therefore μ for rapid alternation is certainly less than the static μ. How much less I have no definite idea. I think, however, that for such frequency of alter nation as occurs in a transformer, say, it is not much less. As to the static value, if your wire is annealed, it may be anything from 3,000 downwards to, say, 100, according to the particular value of $\mathfrak{H}$ at the place considered. If your wire is hard-drawn, it may be anything from about 500 downwards, according to the value of $\mathfrak{H}$. Take an example: a wire four millimetres in diameter, carrying 10 amperes, $\mathfrak{H}$ at the circumference will then be 10 C.-G.-S. This in an annealed wire would make $\mathfrak{B} = 13{,}000$, giving $\mu = 1{,}300$, about. In a hard-drawn wire μ for the same force might be about 500. At points nearer the axis, where $\mathfrak{H}$ is less, μ would (in the soft wire) be at first somewhat greater, and then less as you go nearer still to the axis. I should say that for soft wire $\mu = 1{,}000$ would be a fair average value, and for a hard wire $\mu = 300$ or 400."

33. It will be seen that he suggests a probable value intermediate between the extreme values I had previously made the calculation for; and that for the wires used $\mu = 400$ is a likely value for oscillations such as occur in transformers. But then these oscillations are only a hundred or two per second. Neither Prof. Ewing nor any one else is able to say what the value of μ will be for currents alternating at the rate of a quarter million per second. It would naturally occur to anyone that my experiments themselves should, when calculated out, be able to furnish the appropriate value of μ; and so I hope they will, but they cannot give a value at all closely, because an enormous difference in μ makes but little difference in the length of the B spark. The table printed last week shows that it makes but little difference, at least for cases when the second approximation is easily applicable; and a further theoretical discussion of the point brings out the same thing. There is this advantage about the fact, however, that it is not necessary to know the value of μ at all closely in order to make calculations. It may be asked why I do not determine μ for the particular wires used by direct experiment. It would be easy to determine the μ appropriate to steady longitudinal magnetisation, but this has no connection whatever with the μ appropriate to magnetisation in concentric cylinders alternating hundreds of thousands of times a second. *A priori* one could not say that for such a case as this μ is any greater than unity, but I hope that the experiments will enable us to pronounce on this point one way or another.

I may say that in writing these articles I have not done the calculations beforehand. I am making them as I go along, so as to test the theory by the facts whenever we have data sufficient to make an application of theory possible. The agreement so far found is sufficiently encouraging to make us willing to write out the theory a little more fully, so as to investigate all the circumstances on which the length of the spark alternative to a given conductor in a given circuit depends.

Second Approximation Theory Further Worked Out.

34. In § 4 a general notion of what is necessary for the second approximation to the alternative spark length is suggested, but it is not worked out in that first article. Now that we have a case for which it seems very clearly to apply we must proceed to work it out further.

The principal effect of resistance is the increase of impedance; the effect next in importance is the damping out of the vibrations. It being tolerably certain that the current must rise to a maximum before a critical B spark can occur, a quarter period, or $\frac{\pi}{2n}$, has to elapse between the A and the B spark. Hence the potential available for the B spark is (*see* § 2)

$$V = P_0 C_1 e^{-\frac{\pi m}{2n}} \quad . \quad . \quad . \quad . \quad . \quad (9)$$

Now,
$$C_1 = \frac{V_0}{n(L + L_0)} = \frac{V_0}{p + p_0}, \text{ say,} \quad . \quad . \quad (10)$$

Hence,
$$\frac{V}{V_0} = \frac{P_0}{p + p_0} e^{-\frac{\pi m}{2n}} \quad . \quad . \quad . \quad . \quad . \quad (11)$$

So, if we neglect damping, the ratio of the B spark to the A spark is as the total impedance of the alternative path is to the inertia part of the impedance of the whole circuit.

35. The first approximation, § 3, equation (4), gave us for the ratio of the two sparks

$$\frac{p_0}{p + p_0}$$

The second approximation, without damping, gives us

$$\frac{P_0}{p + p_0};$$

whose numerator contains not only the inertia part of the impedance of the alternate path, but the resistance part as well.

Suppose we call the inertia part of impedance "inertia" simply; and the resistance part let us call "throttling," so that (impedance)^2 = (inertia)^2 + (throttling)^2.

The throttling of the whole circuit write

$$R_0 + R = \sqrt{n}\{\sqrt{(\tfrac{1}{2} l_0 \mu_0 r_0)} + \sqrt{(\tfrac{1}{2} l \mu r)}\} = (a + b)\sqrt{n}, \quad . \quad (12)$$

where $a^2 = \frac{1}{2} l_0 \mu_0 r_0$, and is proportional to both the magnetic permeability and the ordinary resistance of the alternative path; while b^2 represents the same thing for the rest of the circuit.

Digitized by Google

We have also the equations,

$$P_0^2 = p_0^2 + R_0^2 = n^2 L_0^2 + n a^2 \quad . \quad . \quad . \quad (13)$$

$$m^2 + n^2 = \frac{1}{S(L+L_0)} \quad . \quad . \quad . \quad . \quad . \quad (14)$$

$$\frac{m}{n} = \frac{R+R_0}{2p} = \frac{a+b}{2\sqrt{n(L+L_0)}} \quad . \quad . \quad . \quad (15)$$

It is cumbersome and unnecessary to combine all these equations with absolute accuracy; but quite inappreciable error will be made by using the approximations

$$n = \frac{1}{\sqrt{\{S(L+L_0)\}}} - \frac{(a+b)^2}{8(L+L_0)^2} \quad . \quad . \quad (16)$$

$$P_0 = n\sqrt{(L_0^2 + a^2\sqrt{S(L+L_0)})} \quad . \quad . \quad (17)$$

and

$$\frac{m}{n} = \frac{(a+b)S^{\frac{1}{2}}}{2(L+L_0)^{\frac{1}{2}}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (18)$$

Hence,

$$\frac{V}{V_0} = \frac{L_0}{L+L_0}\sqrt{\left\{1 + \frac{a^2}{L_0^2}\sqrt{S(L+L_0)}\right\}} e^{-\frac{\pi(a+b)S^{\frac{1}{2}}}{4(L+L_0)^{\frac{1}{2}}}} \quad (19)$$

This clearly shows the relation of the first approximation (the term outside the square root) to the second. The smaller the capacity of the condenser (other things being the same), the better serves the first approximation.

36. By means of this formula, it is easy to see how the ratio of the B spark to the A spark varies with the different arbitrary variables, L, L_0, S, a, and b.

Iron or Lead versus Copper.

The thing which most interests us is to examine how the B spark depends upon the resistance and magnetic properties of the alternative path—that is, how it varies with a, since $a = \sqrt{(\frac{1}{2} l_0 \mu_0 r_0)}$.

So take logarithms of (19) and differentiate, abbreviating

$$\sqrt{S(L+L_0)} \text{ to } \frac{1}{n};$$

then

$$\frac{1}{V}\cdot\frac{dV}{da} = \frac{a}{n L_0^2 + a^2} - \frac{\pi}{4(L+L_0)\sqrt{n}} \quad . \quad . \quad (20)$$

This clearly shows that when the alternative path is short, $\frac{dV}{da}$ is negative, and that hence the B spark is shortened by an increase in either its resistance or magnetic susceptibility; but that, as a increases, $\frac{dV}{da}$ passes through an insensitive stage, and ultimately becomes positive. When this is the case, the length of the B spark is increased by increasing r or μ.

The intermediate insensitive condition $\frac{dV}{da} = 0$ is attained when

$$a^2 = n\left\{\frac{4}{\pi^2}(L+L_0)^2 - L_0^2\right\} \quad . \quad . \quad . \quad (21)$$

that is, approximately, when

$$P_0 = \frac{2}{\pi}(p+p_0) \quad . \quad . \quad . \quad . \quad (22)$$

or, in other words, when the undamped potential available for the B spark is about two-thirds that available for the A spark.

Under these circumstances (which are very probable ones) a change in the material of the alternative path from copper to iron or lead makes hardly any difference.

The statement (21) for the insensitive condition may be also written, approximately,

$$R_0^2 = \frac{4}{\pi^2}\left(p_0 + p\right)^2 - p_0^2 \quad . \quad . \quad . \quad . \quad (23)$$

If the throttling of the alternative path is greater than the square root of the difference of the squares of $\frac{2}{\pi}$ times the inertia of the whole circuit and of the inertia of the alternative path, then a further increase in its r or μ will diminish its efficacy as an alternative path; but so long as the throttling is kept less than the above value, then the worse a conductor, or the more magnetic its substance, the better an alternative path will it afford.

Thus, the apparently abnormal fact that under certain circumstances thin iron serves as a better alternative path than thick copper (actually *because* it has a higher resistance and a higher value of μ, and thereby damps out the vibration sooner) is fully explained; and the circumstances under which iron ceases to be better and becomes worse than copper are completely specified.

(To be continued.)

THE WESTINGHOUSE COMPANY.

(Continued from page 131.)

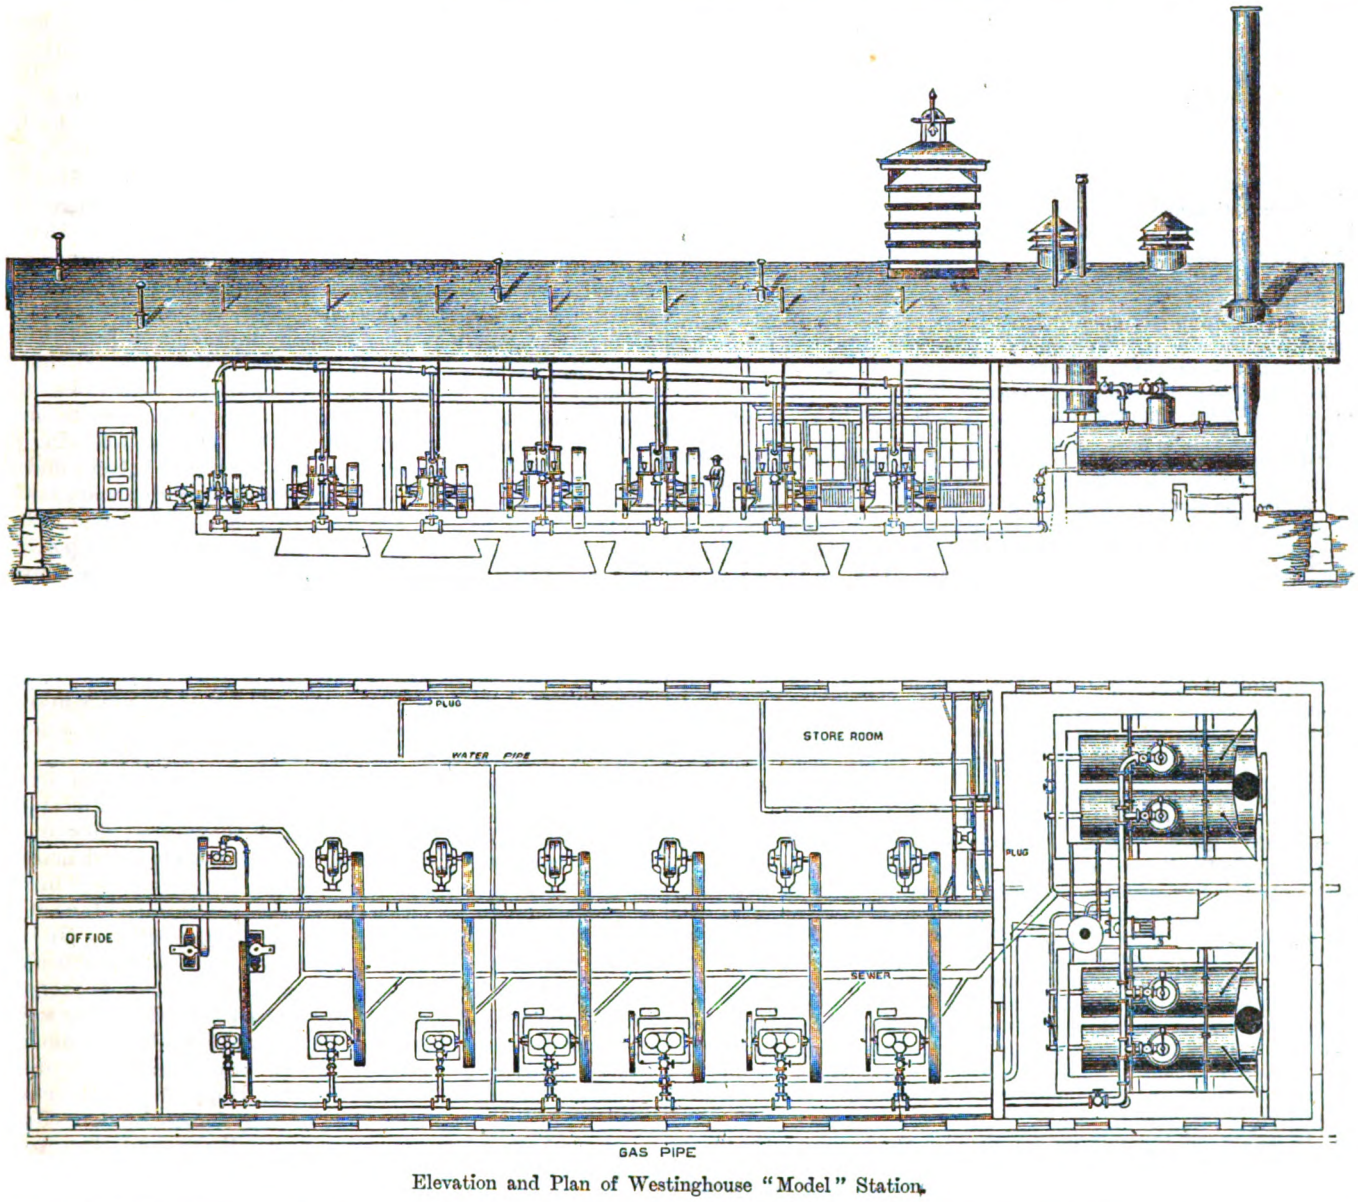
The central lighting station at East Liberty, Pennsylvania, is considered a "model installation" of the Westinghouse Company, and is illustrated in the adjoining engravings. The following description is furnished by the company:—

"The arrangement of the station is clearly indicated. It is a substantial but inexpensive one-story building of brick, containing the offices of the company and the store room for material in addition to the dynamo and boiler room. The plant at present has an aggregate capacity of about 8,000 lights. Dynamos and engines are on the same floor, every part of which is constantly under the eye of a single attendant. Both engines and dynamos stand on brick foundations, the floor itself being of cement. Each engine is belted direct to its own dynamo, no power being wasted in transmission, and the subdivision into units enables the wide fluctuations of load to be met by stopping and starting each engine and dynamo as needed, thus operating the whole station under the highest possible economical conditions at any moment. The steam pipe is brought along the engine room overhead, and the engines exhaust into a main laid in a covered trench underneath the floor, every part being accessible. All drips and overflows are run into a sewer. Two exciters are provided, as shown on the left of the dynamo room, each adequate to supply current to the entire station, and each driven independently by its own engine. But one engine and exciter is, therefore, run at any time, the other standing ready as a relay in emergency. Moreover, the position of the engines and exciters is such that, by changing a belt, either engine can drive either exciter, and thus the chance of possible stoppage is reduced fourfold. We regard this latter arrangement as representing the best possible engineering, and would strongly urge it upon every station of any considerable magnitude. Two overhead travelling cranes traverse the whole length of the building over the engines and dynamos.

"In a station so arranged the labour is reduced to a minimum. With natural gas, of course, but one fireman is required, or firing with coal two firemen will be on duty in the first run of the evening, and one in the second run. But one attendant is required in the dynamo room at any time, the lightness of his duties permitting him to give all necessary attention to the engines, dynamos, exciters, and switch-board. The service from this station covers a very extended area, comprising the business portion of the city, which lies within an average distance of half a mile from the station, ramifying through an extended series of residence streets of the better class, and carrying one special line out as far as the distant suburb of Swissvale, the last lamp being at a distance of four miles and a-quarter from the dynamo."

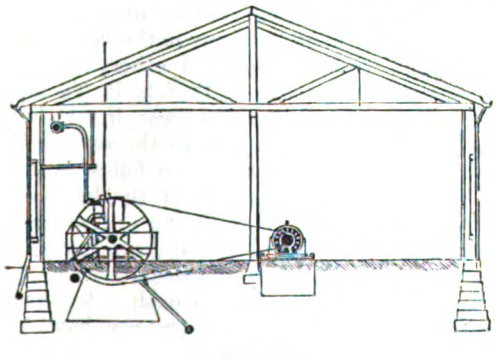
One of the most interesting features of the Westinghouse system is their incandescent street-lighting plant, though it is one which is not suited to existing conditions in this country. As soon, however, as high candle-power incandescents of *moderately high voltage* are able to compete with arc lights in the matter of expense, then we believe that this system will afford the *beau ideal* of electric street lighting. In this arrangement 20 lamps, usually of 25 candle-power, and each taking 50 volts, are placed in series upon a loop line between the 1,000 volt mains, each lamp being shunted by an impedance coil. The coil is so proportioned that it takes a very small current while the lamp is burning, but if the filament breaks, *very nearly* the whole

Digitized by Google



Elevation and Plan of Westinghouse "Model" Station.

current still passes through. Consequently the extinction of any one lamp has very little effect upon the rest, but the extinction of several tends to *diminish* the brilliancy of those remaining alight, an effect which it need hardly be said is the reverse of that attained in other multiple-series systems. This system, therefore, "not only consumes power



End Section.

in exact proportion to the total effective candle-power realised, but becomes self-protecting to the fullest extent." The flexibility of the alternate current is again exemplified by the fact that any desired economy may be attained in the leads by introducing a more or less considerable drop in potential, and compensating for this by placing 21 lamps in series on the loops nearest the station, and 19 in series on the more remote loops. If more convenient the loops may be taken off the general service mains, and may then leave from any point on one main and return at any point on the other. In Staten Island, N.Y., no less than 2,000 street lamps are served on this system from one station, the wires extending over a district 12 miles in length.

The Westinghouse Company recommend the exponents of its system to undertake the wiring of houses *free of charge*. This advice is scarcely likely to prove acceptable in this country; but the following remarks upon the lighting of shops may be read with advantage:—

"*The Lighting of Shops.*

"In commercial lighting, stores may be divided into three classes with respect to the degree of illumination. To the first class belong dry goods, drugs, hats and caps, and furnishing goods. To the second class belong crockery, groceries, boots and shoes. To the third class belong hardware and furniture. These are the leading branches of trade, and other lines may be judged of by their similarity in characteristics to the above.

"Taking the 16 candle-power lamp as a standard, high illumination will be secured by employing in the first class one lamp to every 100 square feet of floor surface, in the second class one lamp for every 150 feet, and the third class one lamp to every 200 square feet of floor surface. When lamps of larger candle-power are used—which, indeed, is preferable—the amount of floor space assigned to each lamp will be practically in proportion to its rated candle-power.

"Stores usually average from 18 to 22 feet in clear width. For convenience we may then place the 16 candle-power lamps in stores

Digitized by Google

of the first-class in two rows over the counters, the lamps being 6ft. 6in. from the floor and 10ft. apart. In stores of the second-class the lamps should be 15ft. apart, and in those of the third-class 20ft. apart. In stores less than 15ft. in width, the most economical treatment as well as that which produces the best effect, is to place a single row of lamps in line through the centre of the store, the lamps being suspended 7ft. high and from 6ft. to 12ft. apart, according to the class to which the store belongs. Upon entering the store the eye of the customer sees all the lamps at a single glance, and the illumination appears more liberal than if the same number of lamps were placed in two rows and twice the distance apart.

"Practice has demonstrated, however, that a better general effect as well as economy in first cost is secured by the use of lamps of 50 or 75 candle-power either against the ceiling or at least as high as 10ft. from the floor. Such lamps should be backed with slightly concave or slightly convex opalescent reflectors, according as the nature of the goods requires a concentrated or diffused light. In stores of the first class these lamps are to be placed at intervals of 20ft., in the second class of 30ft., and in the third class of 40ft.

"These large lamps will always be placed in a single row down the centre of the store, except in those of extreme width. As a rule, the wider the store the higher the lamp should be placed. It is sometimes contended that a 16 candle-power lamp, hung low over the counters, and backed with a porcelain, or other shade, will give the best illumination for the sale of counter goods. This, if true at all, is limited to dry goods and fine wares requiring close inspection. Even with this class of goods, however, the large lamps placed high afford a better general diffusion of light more nearly approximating sunlight. The large lamp, moreover, produces a much greater general illuminating effect in the store. It throws its light upon the shelf, goods, and ceilings, getting the benefit of general reflection and diffusion in a manner which cannot be accomplished by the use of low-hung small lamps, the light of which is cut off from the upper shelves and ceilings altogether.

"A very important consideration in connection with the use of the large lamp is the fact that the first cost of interior wiring is considerably lessened by a reduction in the amount of labour in proportion to the lesser number of outlets, and by the saving in the first cost of lamps, sockets, and other material. The size of wire will be the same in each case for a given total candle-power, but the other material is greatly reduced in relative cost. Again, the use of small and low-hung lamps implies the use of a key socket to each lamp, and it is probable that the slight jar produced in turning the key may sometimes machanically fracture the filament of the lamp, especially when weakened by old age. When large lamps are used in or near the ceiling, the entire circuit is controlled by a branch switch remote from the lamps. The opening or closing of the switch, therefore, communicates no jar to the lamp, and its life is apparently prolonged.

"In laying out the interior wiring for a store, much good judgment can be displayed. In general terms, the main illumination of the body of the store is controlled by one switch, the show window illumination by another, and the watch lights by a third."

There are other features of great interest connected with the Westinghouse system, such as the Shallenberger meter* and the Tesla motor,† but as we are not at present in a position to add anything of value to the information which has already appeared in our columns, we now for the time being take leave of the subject.

REVIEWS.

Die Accumulatoren fur Elektricitat. By Dr. Edmund Hoppe. [Berlin: Julius Springer. 1888.]

Dr. Hoppe has produced a most interesting and readable book on that much belauded and equally well abused subject the secondary battery. It is written rather from the historical and scientific than from the practical point of view, and it is the more valuable in that the author does not appear to have any pet theories or fancies of his own, but gives a clear and well-digested account of other experimenters' work in a spirit of strict impartiality. That Dr. Hoppe does not altogether believe in the commercial battery man may be gathered from the quiet remark in the preface that "in the matter of accumulators, as in most things electro-technical, there has been much swindling," which is followed by another, "that manufaturers' tests are but seldom given in this book."

The first half of the work might have been aptly called a history of polarisation from the earliest times to the end of the Middle Ages. Beginning with the discovery of the fact by Ash and Humboldt, we have an excellent *résumé* of the work done by the early experimenters, such as Volta, Ritter, Davy, Grotthus, Faraday, &c., up to the later period when such work was mostly in German hands. This part of the book bears evidence of considerable research on the author's part, the references to old literature being copious, while from time to time are given lists of articles in various publications bearing on the subject in hand. Dr. Hoppe considers that all useful investigation on polarisation was for some twenty years turned into a wrong channel and wasted by Erman's "discovery" of unipolar induction. One can well imagine what a mystery such a phenomenon must have been to the scientific world with the scanty knowledge then at its disposal. Indeed, even with our present text-books there would probably be some strikingly original answers to an examination question such as this:—Explain the following phenomena. A wire connected to the + pole of a battery and also an earth wire are stuck into a piece of very dry soap, but not touching each other. The positive pole is then found to be at zero potential, and the negative pole at full negative potential. The same is repeated reversing the poles, with the converse results. Wires from both poles, but no earth wire, are now stuck into the soap, and this has no effect on the potential of the poles; but if the earth wire be now also stuck in, even quite close to the positive wire, the negative pole falls to zero, while the positive comes to full potential. Any examiner in search of useful misinformation might, we fancy, acquire a goodly store in the answers he would receive.

With the large amount of previous work shown by Dr. Hoppe in view, one feels the truth of the saying that most great modern discoveries are not invented, they grow, they are "in the air," and come to the front as soon as there is a demand for them. In fact, one might define the "first inventor" in these cases as the man who first shows the practicality of what previous investigators have shown the practicability. He by no means necessarily himself knocks the $b+e$ out of practicable—that is as often as not left to some subsequent worker—but merely shows that they *can* be removed. In this sense we may consider Faure as the "first inventor" of the accumulator, though all the scientific honour of the discovery is due to Planté, with whose investigations Dr. Hoppe begins the modern section of his book, under the heading of construction of accumulators. From Planté we come to Faure, and then to the long array of "inventors" and reinventors who have rushed to the Patent Office with their crude and often untested ideas. Amongst all this chaff we find, of course, the few grains of wheat which have survived to the present day, but they are lamentably few.

In this section there is a list of the German patents on accumulators (most of which are marked "lapsed"). It would add completeness to the book if those of other countries were given also; though, as the author remarks, in the case of most really valuable foreign ideas the German patent is applied for. The chapter on the chemistry of the lead accumulator will probably be read with as much interest as any in the book. The theories of Gladstone and Tribe, Aron, and others are given pretty fully, and finally the remarks of Prof. S. P. Thompson at the Society of Telegraph-Engineers last year, in which he applies the crucial test of the E.M.F. due to the various theories of action. Should anyone feel inclined to follow in his footsteps there will be found on p. 171 a table of the heats of combination of most of the compounds occurring in practice of Pb, H, O and S, besides those of several other components of possible batteries. The table is due to Naumann. The question of efficiency tests is gone into at some length. A page of matter and the integration of the tail of a curve are, however, scarcely necessary to show the inadvisability of draining a cell to its last drop of current in such tests. Two lines touching the consequent disintegration of the plates is all that is required, and more to the point. Dr. Hoppe very rightly stands out here for efficiency in watt—and not in ampere—hours. Results are still often given in the latter, because no doubt they sound so much nicer. There is one cell mentioned in this chapter, by the way, which gives *more* watt hours yet *less* kilogrammeters

than another; whether the slip is Dr. Hoppe's or due to Mr. Fitzgerald, on whose authority the figures are given, we cannot say.

When Dr. Hoppe gets to purely practical matters, such as installation work, he is not quite so happy. He only devotes a few pages at the end to this subject, and for the sake of the goodness of the rest of his book let us hope he may be forgiven his sketch of an installation with plugs instead of switches and resistances between the batteries and lamps.

In future editions, which we have no doubt will be called for, we hope we shall find a full alphabetical index of matter instead of inventors' names only, as this is an important matter in what will, no doubt, become a standard work of reference; and in conclusion we heartily congratulate Dr. Hoppe on the successful way he has carried out his intention in the preface to "collect into one book all the scientific work on accumulators up to the present time."

The Elements of Electric Lighting, including Electric Generation Measurement, Storage, and Distribution By PHILIP ATKINSON, A.M., Ph.D. (New York: D. Van Nostrand, 1888.)

This book makes scarcely any pretension to rank as a scientific treatise, but aims at setting forth the foremost facts pertaining to electric lighting in plain language. In this the author may be said to have achieved a moderate degree of success, though his explanations of elementary theory, as, for instance, the relations between E.M.F., current, and resistance might easily be more simple without being less accurate. He describes a good many types of dynamos, and goes pretty fully into constructive details, although numerical relations are carefully avoided. All the continuous current machines alluded to are American—at least in origin—but the somewhat remarkable fact is brought out that the United States has hitherto produced only one alternating-current dynamo — the Westinghouse. The Siemens, Gordon, and Lontin dynamos, therefore, find a place in these pages; the machines of Ferranti, Mordey, and Kapp will doubtless find a place in the next edition. A fairly complete account of the Westinghouse system is given, with some capital drawings of transformers.

A short chapter is devoted to instruments in practical use for measuring current and E.M.F., and this is followed by a fairly good chapter entitled "Arc Lamps." A much greater space than usual is devoted to carbons, and the Liepmann process of manufacture (described in *The Electrician* of Nov. 18th, 1887) is dealt with at some length. The title of the chapter is, after all, somewhat of a misnomer, as only one arc lamp in practical use receives any mention. The chapter on incandescent lamps is written from the American point of view. It is true that nearly half a page is devoted to the "Swan Carbons," but not a word is said which would lead a novice to suppose that the priority of Edison had ever been challenged. The chapter on the Storage Battery is one of the best in the book, although it seems necessary to say that the chemical action which goes on in the cell is in all probability somewhat less simple in character than is here set forth. It is well known that in the Julien cell an alloy is used instead of pure lead. Dr. Atkinson says that this alloy consists of 94·5 per cent. of lead, 4·2 per cent. antimony, and 1·3 per cent. mercury; we think, however, that this recipe is only to be found in the patent specification, and if we are not mistaken, no mercury is actually employed in practice. A wide field for research exists in the discovery of alloys suitable for secondary battery plates, but, unfortunately, very little theoretical knowledge is available to guide the experimenter.

The author has a good deal to say about "electricity as a mode of molecular motion;" but in a book of this character the subject is, of course, treated from a purely physical standpoint, and, hence, that class of difficulty which appeals to Thomson, Lodge, or Heaviside does not present itself. The chapter in question contains one extraordinary slip to which it seems desirable to call attention. The author in considering thermo-electric action writes as follows (the italics are our own):—"The capacity of bismuth for heat known as its specific heat is 0·03, and that of antimony 0·051 . . . . *and the temperature of each when heated or cooled from the same source varies in the inverse ratio of its specific heat; hence, at the heated junction the temperature of the bismuth rises above that of the antimony, and at the cooled junction falls below it.*" We are at a loss to account for so competent a physicist as Dr. Atkinson falling into such a very palpable error. It is scarcely necessary to explain that when any number of bodies are heated or cooled by radiation the ultimate temperature which each assumes depends upon its own radiative power, and not upon its specific heat. The latter only determines the *quantity* of heat to be absorbed or radiated—and hence the *time* necessary—before the final temperature is acquired.

If there be any connection between specific heat and thermo-electric power it is probably of a very recondite nature, and, anyhow, it is safe to say that it is not of the kind assumed by the author. There are other passages in this chapter which lead us to think that pure science is not the author's strong point, and the book would be decidedly improved by its exclusion from subsequent editions.

We may remark, in conclusion, that the work gives a fairly comprehensive survey of the "paraphernalia" of electric lighting, and may be usefully read by anyone who is in want of general rather than theoretical or technical information on the subject.

Electric Bells, and all About Them. By G. R. BOTTONE. (London: Whittaker and Co., 1889.)

This handbook professes to be "a practical book for practical men," and the claim is one which we need have no hesitation in endorsing. Anyone desirous of undertaking the practical work of electric bell fitting will find here everything, or *nearly* everything, he needs to know. On the first page he learns something about the Greek word for "amber," and on the last he is earnestly cautioned to keep his binding screws well tightened up. The intermediate pages are devoted to the detailed consideration of various types of batteries, bells, indicators, switches, pushes, and relays, concluding with a useful chapter on "Wiring, connecting up, and localising faults."

In the chapter on batteries we could perhaps have spared the sections devoted to Smee's and other cells, which no one would ever dream of using for the purpose. It would also be useful if the author had given some indication of the minimum current required to work the various apparatus described. The number and size of cells is always a difficulty to the inexperienced bell-hanger.

In conclusion, we may remark that this little book will be welcomed by none more heartily than by the electrical engineers. It is a well-known fact that the members of that profession are nearly always looked upon more or less as frauds by their private friends and acquaintances owing to their manifest and deplorable ignorance about the important subject with which this work so ably deals.

MEETINGS OF SCIENTIFIC SOCIETIES, &c.

(To night) FRIDAY, December 14th.

INSTITUTION OF CIVIL ENGINEERS.

7:30 p.m. Students' Meeting. "The 26-Knot Spanish Torpedo-Boat 'Ariéte.'" By JULIAN KING-SALTER, Stud. Inst. C.E.

MONDAY, December 17th.

SOCIETY OF ARTS.

8 p.m. Cantor Lecture. "Light and Colour." By Capt. W. de W. ABNEY, C.B., F.R.S. (Lecture IV.)

TUESDAY, December 18th.

INSTITUTION OF CIVIL ENGINEERS.

8 p.m. Ordinary Meeting. "The Friction of Locomotive Slide Valves." By J. A. F. ASPINALL, M.I.C.E.

WEDNESDAY, December 19th.

ROYAL METEOROLOGICAL SOCIETY.

7 p.m. Ordinary Meeting, at the Institution of Civil Engineers.

SOCIETY OF ARTS.

8 p.m. Ordinary Meeting. "Standards of Light." By W. J. DIBDIN, F.I.C., F.C.S.

THURSDAY, December 20th.

SOCIETY OF TELEGRAPH-ENGINEERS.

5 p.m. Special General Meeting of Members at No. 4, The Sanctuary, to confirm the resolutions respecting the change of title.

The Electrician.

Published every Friday. Price Fourpence; Post Free, Fourpence Halfpenny

Editorial, Publishing and Printing Offices:

No. 1, SALISBURY COURT, FLEET STREET, LONDON, E.C.

Telephone No. 2714.

All Communications to be addressed to "The Electrician," 1, Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to "The Electrician."

All letters intended for insertion in "The Electrician," or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.

"The Electrician" is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.

"The Electrician" is on sale at the railway bookstalls throughout the United Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.

SPECIAL NOTICE.

Owing to the increase in the number of pages of "The Electrician," in order to partly cover the increased postage, we have been compelled to revise the rates for Foreign Subscriptions, which are now as follows:—

	3 months.		6 months.		12 months.	
	s.	d.	s.	d.	s.	d.
For Foreign Parts and Colonies:—						
Within Postal Union	6	6	12	6	24	0
„ Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7	6	14	6	28	0
The rates for the United Kingdom remain as follows:—	5	0	10	0	19	6

TO ADVERTISERS.

"The Electrician" offers exceptional advantages to Advertisers. **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

Trade Advertisements *intended for the current issue must be handed in not later than First Post on Thursday morning.*

Small Prepaid Advertisements *(for Rates see page xi.) are accepted up to 4:30 p.m. on Thursday.*

TECHNICAL PRINTING.

"The Electrician" Printing and Publishing Company (Limited) *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

The Electricians' Directory.

Royal 8vo. Cloth Boards, 3s. 6d., post free 4s.

At the commencement of each year is issued The Electricians' Directory and Handbook. *The Directory was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

THE DIRECTORY FOR 1889 IS IN PREPARATION,

And new names and addresses are now being received.

VOLUME XXI. OF "THE ELECTRICIAN."

Volume XXI. of "The Electrician" is NOW READY,

Price 12/6, post free 13/6.

Cases for Binding Volume XXI. are Now Ready, Price Two Shillings Post Free, Two Shillings and Threepence.

SPECIAL NOTICE.

With the next number of "THE ELECTRICIAN" will be published as an Extra Supplement a Steel Portrait Engraving of Sir WILLIAM THOMSON, F.R.S., &c., &c., &c., the newly-elected PRESIDENT of the INSTITUTION OF ELECTRICAL ENGINEERS. This portrait is one of the Series which has appeared in the pages of "THE ELECTRICIAN," and which will be continued as occasion may seem to warrant.

THE INTERNATIONAL ELECTRICAL CONGRESS OF 1889.

When the *Société Internationale des Electriciens* (so-called) announced its intention of recommending the Government of France to convene an International Congress of Electricians in connection with the forthcoming Exhibition, we did not feel moved to do more than express a qualified approval. The avowed object and the chief duty of the proposed Congress, as originally set forth, were to "continue the labours" of the Congresses held in 1881 and 1884. But that there exists any pressing need of an International conclave for the purpose indicated we have still to discover. It must, moreover, be admitted that if the Congress of 1889 were strictly confined to the completion or revision of the work of its predecessors, its duties would not be of a very onerous character, nor need its labours be unduly prolonged. It might, if it so pleased, give its august sanction to the use of the term *watt* as the electrical unit of power. That, we believe, is the only electrical unit in common use which has not already received its credentials from this source, and we do not see why it is not as well entitled as its brethren to all the dignity of "legal" and formal recognition. The baptism and definition of the unit of self-induction might also perhaps profitably occupy the attention of the Congress. Then there is the question of the determination

Digitized by Google

of the ohm in terms of the mercury standard. While we do not think that a change in the actual definition of the legal ohm would meet with any enthusiastic welcome—nor could it, indeed, be enforced except with the greatest difficulty and in the teeth of a determined opposition—yet it might, nevertheless, be worth while to take advantage of the Congress to obtain an authoritative expression of opinion as to the value at present most probable. That this value lies somewhere between 106·2c. and 106·3c. is already pretty well known.

Another question of considerable importance, and of the greatest difficulty, is that of a practical standard for the unit of light. The Congress of 1884 accepted M. VIOLLE'S proposal, and defined the unit of light as that given by one square centimetre of platinum at its melting temperature. But although this idea has been ingeniously realised by Dr. WERNER SIEMENS, yet we are not aware that it is at all used in practice, and, in fact, most people have only the vaguest idea of its relation to the standard candle. This latter standard we regard as an interesting case of "reversion to type" as when, in the pre-scientific ages, the length of a Royal arm gave us our yard measure. Seeing that a good deal of excellent work has been done in photometry since the date of the last Congress, and that more than one "standard" has since been proposed—notably the "pentane standard"—we are decidedly of opinion that the subject should be discussed *de novo*. Lightning conductors and earth currents were the only remaining subjects upon which the earlier Congresses passed resolutions; and these were only in the nature of "pious opinions."

In addition to these several topics there are, doubtless, others —some of an academic and some of a practical character—which might be discussed with more or less advantage. In the former category we may name the Theory of Dimensions, which has lately been occupying the attention of our Physical Society, and which undoubtedly stands in need of careful reconsideration. An attempted reformation in this direction would certainly be more effective if it bore the *imprimatur* of an International Congress. In practical affairs it is possible—though we make the suggestion with some hesitation—that the Congress might do well to undertake an investigation of the conditions of personal safety with high-tension currents, both alternating and direct. Although it will be seen that we are not now attempting to indicate the limits within which we think the work of the Congress should be restricted, we may, nevertheless, hazard the opinion that it would be a decided mistake if any endeavour were made to travel very much further afield, and especially if it were proposed to adjudicate upon, or even to discuss, the relative merits of the apparatus and methods connected with the commercial applications of electricity.

Nevertheless, this is exactly what is now proposed to be done. On another page will be found the official programme of the "Preparatory Committee" of French Electricians, whose appointment by the Minister of Commerce we noted some time since. Although we are sincerely sorry to say so, we cannot help thinking that this programme is, to say the least, not a judicious one. In the first place, notwithstanding the division into six sections, it is far too long. It would certainly be impossible to do justice to one-half of the questions proposed in any reasonable space of time. But this is not by any means the worst feature. From our point of view the subjects selected for discussion are in very many cases wholly unsuited for treatment by a body whose functions are—or have hitherto been supposed to be—of a legislative character. It seems to us that the Preparatory Committee has confounded the functions of the Congress with those of the Jury of the Exhibition. If the International Congress of Electricians is to discuss the different methods of automatic regulation of dynamos we shall presently be seeing advertisements of "the automatic regulator, as recommended by the International Congress." Alternate-current motors may *possibly* be a legitimate subject for their attention—though even here we are doubtful—but the comparison which is invited between the relative advantages of alternating and continuous currents is, in our opinion, quite out of place. Most of the other questions proposed in this section—such, for instance, as the efficiency of dynamos and the "possibility of constructing very powerful machines"—seem to us equally unsuitable. Objections of a similar character apply more or less all through the programme. An International Congress of Electricians may perhaps be allowed to say something about International Telephone lines, though the question is really a political one; but why it should be expected to devote its attention to the subject of making joints in telegraph wires, and "how many telephone connections can be made per hour by a single operator," we are at a loss to imagine.

There does not seem to be any reason why a series of meetings for the free discussion of various electrical topics should not be held during the Exhibition, and we are far from saying that an exchange of views between the practical electricians of different countries would not produce useful results. But to indiscriminately confound under the style and title of an International Congress the discussion of mere points of technical or commercial detail, with the deliberations of the leaders of scientific thought upon that limited number of far-reaching questions upon which the agreement of the whole civilised world is really desirable seems to be equally unnecessary and unwise. We most sincerely hope for the success of the Electrical Section of the Paris Exhibition of 1889, and also of the Electrical Congress; but to that end we strongly advise that an amended programme be prepared.

THE SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

The Annual General Meeting of this Society was held last night at the Institute of Civil Engineers, Great George-street, Westminster, when the undermentioned officers and council for the ensuing year were elected:—

Officers and Council for 1889.

President.

SIR WILLIAM THOMSON, F.R.S., D.C.L., &c.

Vice-Presidents.

J. Hopkinson, M.A., F.R.S. | Prof. Ayrton, F.R.S.
William Crookes, F.R.S. | Alexander Siemens.

Members of Council Remaining in Office.

Captain P. Cardew, R.E. | Gisbert Kapp, Assoc. M.I.C.E.
R. E. Crompton, M.I.C.E. | Prof. John Perry, F.R.S.
Prof. J. A. Fleming, M.A. | Sir David Salomons, Bart.
Prof. George Forbes, M.A. | Augustus Stroh.
Sir Douglas Galton, K.C.B.

New Members of Council.

W. Lant Carpenter, B.A. | Prof. S. P. Thompson, B.A.
Sir James N. Douglass, F.R.S.

Associate Members of Council.

Sydney Evershed. | Capt. A. S. Wrottesley, R.N.
Guy Carey Fricker.

Hon. Treasurer.

Edward Graves, V.P.

Hon. Auditors.

J. Wagstaff Blundell (Wagstaff Blundell, Biggs and Co., Chartered Accountants), 12, Delahay Street, Westminster, S.W.
Frederic C. Danvers, India Office, S.W.

Hon. Solicitors.

Messrs. Wilson, Bristows, and Carpmael, 1, Copthall Buildings, E.C.

Bankers.

Messrs. Cocks, Biddulph, and Co., 43, Charing Cross, S.W

Secretary and Editor of the Journal.

F. H. Webb.

THE RECKENZAUN STORAGE BATTERY AND ELECTRIC TRAMCAR.

The design of storage batteries for the purpose of electric traction has occupied Mr. Reckenzaun's attention for a very considerable period, and he has conducted a long series of costly experiments in order to determine the most suitable and practical method of construction. In writing last week on the subject of battery traction we promised at an early date to bring before our readers some results which, so far as we have had opportunity of observing, have impressed us as being distinctly the best hitherto attained. This promise we now fulfil in describing the Reckenzaun battery; and we cannot justify the view we have taken more conclusively than by stating that a Reckenzaun plate in any stage of its formation may be bent to and fro or doubled upon itself without any loss, or any trace of loss, of paste. Anyone who knows how carefully plates of ordinary design have to be handled, and how fatal is any bending or deformation of the plate, will appreciate the significance of this feature in connection with a cell designed not only for rapid variations of output but also to withstand the continual jolting and frequent handling which is inseparable from tramcar work.

The expansion of the active material has been the cause of most of the trouble in storage cells, and this cannot be prevented; it is a necessary result of the oxidation of metals, and no amount of mechanical strength in the grids can stop it. In the early days it was thought that by making parts of the grids thicker and by providing numerous insulating studs or separators between the plates, this tendency to rapid destruction could be prevented. But it was found that stout ribs only aggravate the evil, because when the active material expanded, it stretched the thinner ribs more than the thick ones, with the natural result of "buckling" the plate, and the least movement out of its normal line caused the paste to crack and tumble out in halves. M. Julien and others make use of alloys of lead and antimony, which give a very stiff grid. This answers very well in cells where comparatively low current rates are used, but in thin plates for tramcars it was found that though the grid remained intact, the paste was bound to split and crack in the endeavour to found room for its own increasing volume.

Numerous attempts have been made to cast or roll grids the holes of which were intended to offer concave sides for the better retention of the material, but these processes were attended with great difficulties and expense, and the results obtained do not seem to have come up to the expectations. During the early part of the year 1884, Mr. Reckenzaun struck out a new line of study with two objects in view, viz.:—Firstly, to ascertain whether it would be possible to produce compound plates without providing perforated supports, grids, corrugations, reticulated or other frames. For this purpose he tried various methods of casting pieces of oxide of lead together with lead, and he also tried to cast metallic lead round pellets of oxides. Having satisfied himself that this was possible, the next series of experiments were directed to discover whether and to what extent the *shape* of the oxide entered into the question of ultimate success, and it was found that not only the shape of the oxide, but also the shape of the supporting material influenced the final results of secondary battery plates. It is not difficult to understand that these experiments necessarily extended over a long period, and necessitated the most careful observations to note the relative effects of different arrangements. This process of evolution, however, had the effect of convincing Mr. Reckenzaun of the following facts:—First, cylinders of small diameter and comparatively great length are least liable to distortion, because they expand principally in the direction of their own axis, which is parallel to the surface of the plate; secondly, the minute expansion in the direction of their diameter merely causes more effective contact with the surrounding metal; thirdly, the metal which is cast round the cylinders must be of uniform thickness, and of soft (that is, pure) lead, so as to offer little resistance to elongation.

Some plates of this description which are said to have been in constant use for three years we have recently examined. We have bent these, rolled them up into the form of a cylinder, and unrolled them again without disturbing the active material, or observing any scaling of the plates. The construction is illustrated in the accompanying figure (Fig. 1).

The porous cylinders are $\frac{3}{16}$in. in diameter, and about $1\frac{1}{2}$in. long. After being formed in a mould they are put into cavities in a cast iron chill $\frac{1}{4}$in. distant from centre to centre, and the molten lead is poured in, producing a substantial looking plate. The metallic part of the plate is only $\frac{1}{8}$in. thick, so that the cylinders protrude on both sides, and thus offer a large active surface to the electrolyte.

At the works of Messrs. Stephens, Smith and Co., at Millwall, there is now awaiting shipment an electric tramcar, fitted with these cells, and with the worm and wheel gearing with which Mr. Reckenzaun's name is connected. This car has been built to the order of Messrs. Booth, Ellson and Co., of Melbourne, and it is intended for the Sandhurst and Eaglehawk Tramway, in the City of Melbourne. The car itself is of the best American 2-horse pattern, and was built by Mr. George Milnes, of Birkenhead. The body is so constructed that it can be taken apart for shipment. The machinery consists of two 8 horse-power Reckenzaun motors, each driving an axle through the medium of worm gearing. The motors are collectively capable of yielding 24 horse-power, if required, without undue heating, and they will have to propel the car over gradients of 1 in 20 of considerable length. We have seen this car running and starting on such a grade with perfect ease. The field-magnet coils of each motor are divided into four equal sections, and their ends are joined to a commutator at each platform. By turning this commutator these coils can be automatically coupled in a

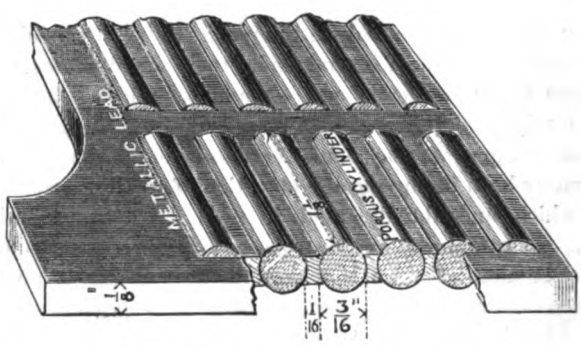

FIG. 1.—The Reckenzaum Storage Battery Plate.

variety of ways; that is to say, the resistances of the motor circuit are varied by coupling the coils all in series, or all in parallel, or by either of the two other intermediate arrangements. Four different speeds and powers are thereby obtained, without interfering with the coupling of the cells. The motors are very compact, weighing 600lb., and measuring 26in. long over the bearings, 22in. wide, and 12in. high. There is ample space for this machine under the floor of the car, leaving 12in. clear between the roadway and the underside of the motor frames. Each motor is supported on a triangular wrought-iron frame, resting on three bearings upon the axles. This arrangement allows a free movement of the axles on uneven rails, without causing undue friction on the bearings of the frame. The spindle of each motor is, moreover, attached to the worm by means of a flexible coupling, so that all the bearings can get considerably out of line without in any way interfering with the driving gear.

The steel worms have a pitch of 45 degrees, so that they can be driven backwards by the wheels; the car can therefore run down even a slight grade (of 1 in 100) by gravity alone. The worm-wheels are of phosphor bronze, and run within a dust-tight cast-iron casing, and this casing contains a quantity of oil, which lubricates the gear automatically without attention for weeks. The top of the casing forms two thrust bearings for the worm to revolve in. We take it for granted that if at ordinary speeds this gearing will give an efficiency as high as 85 per cent., then its positive action, absolute silence, strength, and compact shape render it particularly suitable for street car traction. The usual hand-brakes are used for stopping and going down grades.

Digitized by Google

The storage cells are 72 in number, each made up of 17 plates, giving a capacity of 160 ampere hours. The cells are placed on long boards under the seats. These boards are on rollers, and can be readily drawn out through doors at either end of the car. The cells, with trays, terminals, and all necessary fittings, weigh about two tons. The car, when loaded with 30 passengers, weighs about 7½ tons. It requires about five electrical horse-power, with the full load, to run on the level road at seven to eight miles an hour, and nearly four times that power on a grade of 5 per cent. rise. The car is beautifully finished, both inside and out, and is lit by incandescent lamps.

PHYSICAL SOCIETY.

At the meeting of this Society, held on the 8th inst., the President (Prof. A. W. Reinold) in the chair, Dr. WAGHORNE read a note on

"A Modification of the Ordinary Method of Determining Electro-Magnetic Capacity."

The author stated that the object of his proposed method was to enable the capacity of a condenser to be determined with a fair amount of accuracy, without the use of costly apparatus. The ordinary well-known method is to charge the condenser to a definite potential by means of a battery, discharge through a ballistic galvanometer, and observe the throw d_1. Then observe the steady deflection d_2 when the same battery is connected in series with the galvanometer and an added resistance, bringing the total resistance of the circuit up to a value R, such that d_2 may not differ greatly from d_1. If t is the time of a complete swing of the needle, the capacity in farads will be

$$F = \frac{t\, d_1}{2\pi\, R\, d_2}.$$

To obtain accurate results d_1 must be not the observed throw, but, owing to the effect of damping, this throw increased in a certain ratio determined from the logarithmic decrement, which must, therefore, be found. Secondly, the value of R must be extremely high to make d_1 and d_2 nearly equal. Thirdly, owing to the shortness and consequent stiffness of the suspending fibre, and the effect of this being greater on the throw than on the steady deflection, the value of d_1, corrected for damping, will still be too small relatively to d_2, and must be further corrected by means of torsion observations.

Prof. Ayrton had suggested obviating the necessity of so high a resistance by using only a known fraction of the E.M.F. of the battery when determining the steady deflection, and to diminish as far as possible the error arising from torsion the author had used Mr. Vernon Boys's quartz fibres. The author, however, proposed to overcome the difficulty more completely by reading in the second case the deflection on closing the circuit, which would be double the permanent deflection if there were no damping, instead of reading the permanent deflection directly. The damping, however, in the two cases will be so nearly equal that it is not necessary to allow for it. With this method resistance coils of from 1,000 to 10,000 ohms may be used in conjunction with any suitable sensitive galvanometer, which need not, however, be specially constructed for ballastic experiment. A Pohl commutator or rocking key is very convenient for making a series of observations of the two throws in rapid succession.

The slightly modified form of this commutator adopted by the author is shown in the diagram, which represents the arrangement adopted in the experiments. Let a be the resistance of that portion of the resistance coils to which the condenser terminal is connected, and b the resistance of the portion to which the terminals carrying the steady current is connected.

Then if d_2 is the deflection on closing the circuit, we have, assuming the damping to be the same in each case,

$$F = \frac{t\, d_1\, b}{\pi\, R\, d_2\, a}.$$

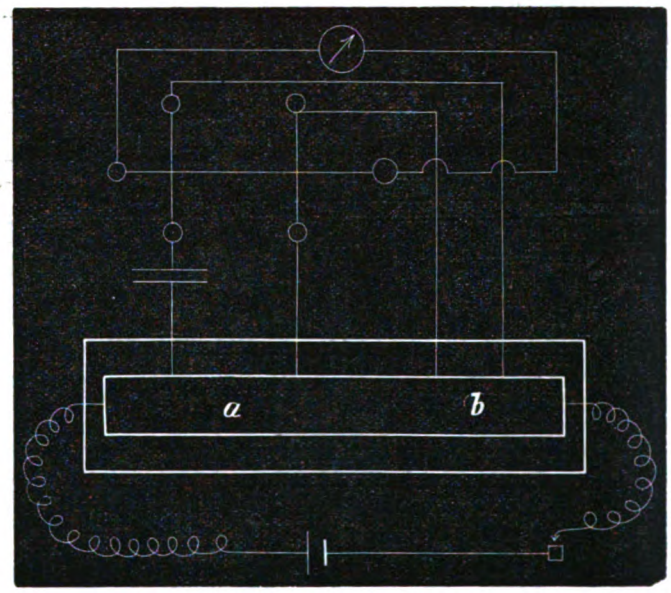
It is not necessary to insert any resistance into the permanent circuit except that of the galvanometer, but the value of this must be known at the temperature of observation.

The author affirmed that in any galvanometer in any way suitable for ballistic purposes, the error arising from difference in damping on the open and closed circuit would be negligible, and he stated that in the case of a galvanometer of 2,000 ohms resistance, which he had been using, the logarithmic decrement was ·0415 on open circuit and ·0428 on closed circuit, giving an error of only 1 in 2,000. He pointed out that the error arising from the stiffness of the fibre was not entirely eliminated as the swing was half a period on closing the circuit, and only a quarter period on breaking it. It was, however, reduced to a very small amount. The period of swing of the needle should not be less than two seconds, as the effects of self-induction on closing the circuit would then become sensible. The author states that he is able to obtain an accuracy within from a half to a quarter per cent.

Prof. S. P. THOMPSON observed that a point which was often lost sight of was the necessity of determining the capacity of the key in measuring the capacities of small condensers. It was advisable on this account to adopt such an arrangement as to make the electrostatic capacity of the key as small as possible.

Prof. AYRTON considered that any method which made it unnecessary to determine the logarithmic decrement would be valuable. He had a faint recollection of trying, in conjunction with Prof. PERRY, a somewhat similar method when in Japan. He believed, however, that it was in some experiments for determining the capacities of substances likely to act as electrolytes, and give an E.M.F. of polarisation.

Mr. SUMPNER expressed surprise at hearing that in the case of the galvanometer used by the author the damping was nearly the same on open and on closed circuit respectively. In the case of a Thomson high-resistance astatic galvanometer with which he was familiar, the logarithmic decrement on open circuit was only about half its value on closed circuit. In this case, therefore, the air damping formed about half of the total effect, while in the case mentioned by the author it would appear that the air damping was practically the whole effect. It would, therefore, be necessary to calculate and allow for logarithmic decrement.



Prof. AYRTON said that Mr. Sumpner's remarks had recalled to his memory that this was exactly the difficulty which they had met with, and which had prevented them from paying further attention to the method. The fact, however, that in spite of neglecting the difference in the logarithmic decrement, the author had succeeded in obtaining results of an accuracy within half or a quarter per cent., appeared to prove that the method was a good one.

Dr. WAGHORNE, in reply, observed that a galvanometer, in which the damping was considerable, would not be suitable, as it would be difficult to determine the time of swing with accuracy. He thought that the logarithmic decrement, having nearly the same value on closed and open circuit in the case of his galvanometer was probably due, in part at least, to the induced currents in the metal framework of the galvanometer when the circuit was broken. The method he explained was intended for the determination of moderately large capacities; only he thought that the elimination of the torsional correction was of more importance than obviating the necessity of determining the logarithmic decrement.

The PRESIDENT (Prof. Reinold), in conclusion, observed that he considered this a useful modification of the ordinary method, as it enabled the capacities of condensers of from half a microfarad to a microfarad in capacity to be directly measured with as great accuracy as could be obtained by comparison with a standard condenser, thus obviating the necessity of an accurate standard condenser.

The Patent, Designs, and Trade Marks Bill.—This Bill was read a third time in the House of Commons on Thursday last week, and on Tuesday the Commons' amendments were agreed to in the House of Lords.

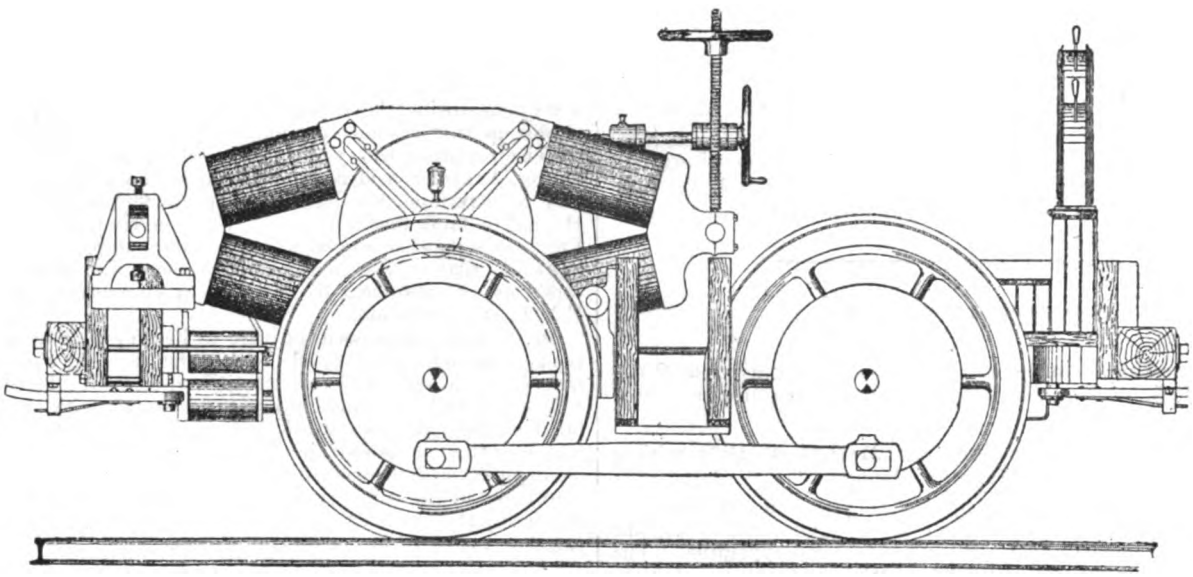
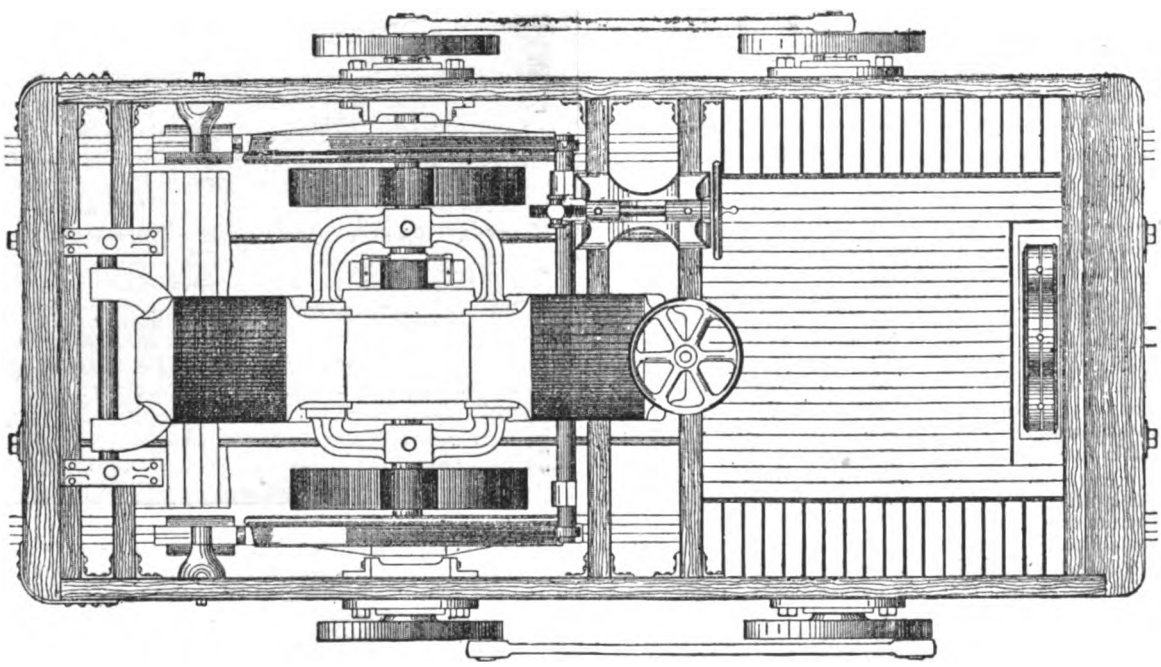
THE "DAFT" ELECTRIC LOCOMOTIVE.



Elevation.



Plan.

We illustrate above two views of the "Daft" 125 horse-power electric locomotive which is now being tried upon the elevated railways of New York. A full description will be found in the letter of our New York correspondent in the present issue.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *December 1st*, 1888.

The question of operating the elevated railways in this city has cropped up again during the past week. The Daft Company, who some time ago began a series of experiments on the Ninth Avenue-road, have now resumed their work, and appear to have obtained some results which must be characterised as satisfactory. When they began their experiments two or three years ago the motor which they put on, the "Ben. Franklin," was not strong enough for the work given it. It was by no means equal to the steam locomotive in use; and thus, although able to handle one or two cars with facility, it was not able to do anything with the ordinary train of some four or five cars loaded with passengers. The motor, as it now stands on the road, has twice as great a tractive capacity as it had before. It weighs about ten tons, and will develop up to about 125 horse-power. The result is that it can haul four passenger cars, with 176 passengers, or a total weight, with the motor, of 77 tons. With eight cars, aggregating 122 tons, it has ascended the maximum gradient on the road, 98ft. to the mile (1 in 54), at a speed of 7½ miles an hour; with four empty cars, making a train of 66 tons, it has maintained a speed of 25 miles an hour, and with three cars of 52 tons it has kept up a speed of 30 miles an hour. Other changes worthy of mention, besides increasing the power of the motor, have been made.

The old "third rail" method with which the name of Mr. Daft was associated has been abandoned for various reasons, one being that the third rail interfered with the operation of the regular steam locomotives, which still perform the service of the road. For the third rail has been substituted a $\frac{5}{8}$th inch copper rod, sustained by insulating brackets, and secured to the

Digitized by Google

guard timbers alongside the track. This conductor is stretched a length of over four miles, from Fourteenth-street to Fiftieth-street, and the whole iron elevated structure is used as a return. The contact is made along the rod by means of brushes. On the motor itself, disc cranks and connecting rods have been added, in order to avail of the adhesion to the rails of four wheels instead of two, and the power is transmitted by friction gear. The new motor used may be described roughly as of the Gramme type, and has two V field-magnets. The power station for the road is situated in Fifteenth-street, about 300 yards from the track, and the current is carried from the generators by insulated wires to the copper rod. A public demonstration of the feasibility of the system was made during the past week, and it was certainly very successful. The night of the trial was one of the dirtiest we have had in New York for a long time. A cold rain storm succeeding a day of heavy snow, accompanied by a strong wind of the blizzard type, made everything as cold, sloppy and greasy as possible. It was an ideal night, however, for showing that the system could operate under unfavourable conditions, and the result was encouraging. A train of cars was taken with a good load of passengers up and down the road, was backed and switched and broken up, and remade, and was pulled and pushed, yet under all conditions the motor responded to the call upon it, and the impression left upon the minds of those who witnessed the test was that electricity was undoubtedly the most desirable motive power for such a road, where, under the present conditions, the smoke, gases, hard coal grit, fine dust and hideous rattle, have combined to make New Yorkers wish that, in spite of their many advantages, such things as elevated roads had never been invented. One result of this successful demonstration on Mr. Daft's part will be, of course, to stimulate the other electrical engineers who have attacked the elevated road problem. But the important point has been gained, I think, that the electrical system as a system is acknowledged by those who have the elevated service in charge to be the best adapted for that purpose. On the night in question several leading officials and stockholders of the road were present, and their appreciation of what they saw was evident to everybody.

We are having lively times just now over the effort made by the United States Illuminating Company to obtain from our New York Supreme Court an injunction restraining the Board of Electrical Control from forcing them to place their wires in the conduits which are being provided in various parts of the city. I have already acquainted you with the status of the matter, and need not, therefore, go into details as to the strength of the opposition made by the United States Company to the work of the Subway Board from first to last. The proceedings at the present time are particularly spicy, from the fact that the company charge that the Subway Board has been guilty of gross favouritism, and that the whole business of the Subway Board is a monopolistic job, the Phœnix Construction Company and the Consolidated Telegraph and Electrical Subway Company, which are carrying on the work under the Board, being practically the Western Union Company, the Metropolitan Telephone Company, the Edison Company, and such individuals as Mr. Maurice B. Flynn. These parties are, it is alleged, operating the subways in their own interests. Going beyond its accusation regarding corruption on the part of the Board, the United States Company alleges that the conduits laid down are suited neither for arc nor for incandescent lighting, and that facilities have not been provided for distribution along the lines of the subway. These statements are supported by a number of affidavits, chief among which is that of Prof. G. W. Plympton, president of the Board of Subway Commissioners of Brooklyn, who believes that no subways have yet been put down that will answer for electric light wires. For its part the Board of Electrical Control, paying little attention to the accusation of jobbery, puts in a number of affidavits showing that the subways are efficient for all classes of electric wires, these affidavits being made by such men as Mr. Barrett, Chief of the Electrical Bureau of Chicago; Mr. J. Elliot Smith, Superintendent of the Fire Alarm Telegraphs of this city; and Mr. Wm. Maver, jun., Electrician of the Western Union Company. Judge Lawrence, who heard the case, however, entered a very strong protest against all this parading of affidavits. The main and only question, it appeared to him, was whether the Board had or had not a legal right to order the United States Company to put its wires underground into the conduits, and he took occasion to have a slap at the experts. "These experts," he said, "always differ. A few years ago I tried a case in which plenty of experts swore that no underground conduits could be constructed in which electrical wires could be operated. Now their ideas have progressed so that all the experts admit that conduits for telegraph and telephone wires are all right. Experts will swear to anything. Dr. Dionysius Lardner demonstrated that a steamship could not cross the Atlantic, and ten days after he published his demonstration the 'Great Western' accomplished the feat. I do not want to have the question of the practical efficiency of the subway thrust upon me in this case." The poor experts, of whom several were present, and who were also represented by strings and bunches galore of affidavits, had the grim satisfaction, however, of hearing the judge go for the lawyers also. The counsel started in very sweetly and glibly showing how well they understood the subject by explaining it to the judge; but before they got very far each time they found it better, after all, to fall back on the specific statements and phraseology of the much derided experts, and thus they aroused the ire of the Court. "Lawyers will persist," he said, "in using ten words where one would do. Why detain the Court with the extra nine words?" Altogether the case has attracted a great deal of attention, the more so because it is seconded by various articles *pro.* and *con.* in the daily papers, each of which feels, of course, that it must have a hand in the fight.

The Telegrapher's Mutual Benefit Association has just held its annual meeting, and it makes a very good report as to the work accomplished. This is an organisation which was started several years ago amongst the operators for life insurance, and it has steadily grown until it has reached a membership in the first division of 3,397, and in the second division of 476, and has a reserve fund of about $73,000. The association has been well managed, and is keenly alive to its responsibilities, not only in the matter of increasing its reserve as much as possible, but as regards extending its area of usefulness. The membership already includes a number of telephone men, and a great number of others who began life in telegraphic work, but have drifted off into other careers, and are to be found in all kinds of positions, chiefly of a prominent and responsible nature. It is now felt that it might not be amiss for the association to include the newer branches of electrical work, and the subject came up for discussion at the meeting. After a period of discussion and agitation, I should not be surprised to see this association, which has done so much good work, placed upon a broader basis, so that it becomes an electrical life assurance association. I do not know whether you have any similar organisations on your side of the water, but on this side, where the telegraphers are in the employ of private corporations, and have no pensions to fall back upon, the association is regarded as doing highly valuable and praiseworthy work.

The coast line of the United States is not a small one, but it begins to look as though very soon it would be girdled by thousands of miles of telephone line, giving a complete system, connected link by link from one end to the other. A telephone service has been put up along the coast of Delaware, and Superintendent Kimball, of the Life Saving Service, now proposes to put one up next March, running along the coast of Long Island, from Coney Island to Montauk Point, a distance of over 100 miles. The work is to be carried out by the Life Saving Corps, and all the preliminary surveying and work have been done. The Long Island line will have some 30 stations, and evidently the work of the Corps will be greatly facilitated. A system has also been inaugurated along the New Jersey coast, which has 23 stations, so that the whole will be operated uniformly and together. The value of the system has already been shown on the New Jersey coast, where formerly dependence was placed on the signal code, which could be used only in fair weather, but now, by means of the telephone, life-saving crews can be summoned at once to any point where they may happen to be needed, and in this way the efficiency and the mobility of the force are greatly increased.

Digitized by Google

In connection with what I have said above regarding our elevated system, it is a little bit interesting to note that in Philadelphia, where the cable roads have been put in as a substitute or makeshift for rapid transit, the National Conduit Company is about to make tests of an electric motor on the Traction Company's line. The Philadelphia Traction Company operates a number of miles of cable road, and hence the fact that it is willing to lend its aid for tests with electric motors is rather significant. The president of the company insists that there is no intention to substitute electric power for the cable, but the experience with the cable system in Philadelphia has been such as to lead one to believe that the promoters are not very affectionately devoted to it. The president of the Traction Company is quoted as saying that they regard the cable system as filling all necessary requirements as a motive power with the single exception, that it does not furnish independent power for each car. "This is overcome in the storage system, and becomes the great point of recommendation for that plan." In other words, while the Traction Company proposes to go on with its cable work, it looks to electricity for the final solution of its troubles and difficulties.

NOTES FROM VIENNA.

(FROM OUR OWN CORRESPONDENT.)

VIENNA, *Dec.* 3rd.

The Government have now definitely decided on building the trunk line from Vienna to Prague for telephonic purposes. This line is to be run quite separately from the telegraph lines, thus ensuring an absence of many disturbing influences, and it is to be built of 3-millimetre bronze wire. The Government has been much helped by the Telephone Company of Austria doing all that is possible to meet their wishes. In Prague this company is going to very great expense in refitting their exchange with a new switch-board, which will be able to serve single and double lines, and which will enable their subscribers to at once make use of the new trunk line. Other trunk lines are to be carried to Prague, such as a line from Teplitz, another from Richenberg and Brunn, so that soon a large number of trunk lines will join in Prague and connect most of the large manufacturing towns in Bohemia. The exchange in Prague is also growing at a rapid rate, as all those exchanges are doing which belong to the Telephone Company of Austria. The sending of telegraphic messages by telephone to the telegraph office is being made much use of by the company's subscribers. In Prague alone over 28,000 have been sent and received by them since 1st January, 1888. In Trieste the Telephone Company of Austria are also fitting up a new board to greatly improve their service. The calls in Trieste average per subscriber about nine per day, a very high percentage. This new board is being made by the Consolidated Telephone Construction and Maintenance Company, in London, and is a greatly improved board, based on the old board known as the "Consolidated," with many improvements suggested by Mr. R. Howard Krause, the General Manager of the Telephone Company of Austria (Limited). It will take very little room, can be extended to serve 1,200 subscribers, and is a board which comes as near doing the work of a multiple board as such a board can possibly be got to do without being a multiple, and will cost, of course, much less than a multiple would. It is believed that the Consolidated Company intend adopting this type for their switch-boards. The Vienna Company are also rapidly extending their system, and have fitted up their exchange for 2,000, and are extending it to 2,500. They are laying cables for 800 new subscribers, and have all the lines taken up already. On November 26th the first Government exchange was opened in Warnsdorf, in Bohemia, a considerable manufacturing town. This exchange was opened with forty subscribers. Next year the Government hope to open Salsburg, Gablonz, Karlsbad, and some others; but they intend to confine their attentions principally to trunk lines between towns.

On November 10 the Electro-Technical Society of Vienna visited the central station belonging to the Imperial Continental Gas Association in the Schenken Strasse, after having visited the Opera House and the Burg Theatre. The effect on the minds of the visitors, which included many who had hitherto been anything but friendly to the gas company, and who especially disliked the fact that this company ordered most of their machinery in England, was so overwhelming that the society has now addressed the following letter to the gas company:—

"Vienna, November 21, 1888.

"To the Imperial Continental Gas Association, Vienna.

"You have earned the very special thanks of all the members of the society who joined the excursion on November 10 through your very kind invitation, as thereby you enabled them to study an electrical installation which is exemplary, and which is, in its way, equal to the grand arrangements in the two Court theatres. All three installations together are worthy of every praise in the careful thinking out of every, even the smallest, detail of the switches, measuring and controlling apparatus, and are a work which will be a mark in the development of electrical science in Vienna, and in future Vienna will be the centre for all experience regarding accumulators." The letter ends with thanks for the special arrangements made to receive the society, and with thanks to the officials of the company, Mr. Findon, Dr. Teltscher, and the engineers.

The Houses of Parliament in Vienna are to be lit up with the electric light, and Messrs. Siemens and Halske have secured the contract, giving a guarantee for ten years. The well-known summer resort near Vienna, Vöslau, is also to be lit up by electricity, and some of the other numerous country towns round Vienna are sure to follow its example.

The new German "Volk's Theatre" is also to be lit up by the electric light, and Messrs. Ganz and Co., of Buda-Pest, have obtained the contract. The syndicate of the theatre do not pay for the installation, but only a fixed price per lamp, amounting to about 20,000fl. a year, and after a certain number of years the installation is to become their property.

LATER.

Messrs. Ganz and Co., of Budapest, are thinking of opening a central electric lighting station in Vienna, and have applied to the Town Council for permission to lay cables and open the streets. The Committee of the Town Council recommended that this permission be granted on the same terms as to Messrs. Siemens and Halske, but have in this case extended their recommendation that this permission hold good for an eventual second central electric lighting station to be built by Messrs. Ganz and Co.

SCANDINAVIAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

COPENHAGEN, *Dec.* 1, 1888.

The electric light is being installed at present in the Swedish town of Helsingborg, where a central station is being erected in the railway station at the company's expense. The platforms are being lighted by arc lamps, and some of the other localities by incandescent lamps, but the whole of the buildings have not been taken in hand yet. At the harbour arc lamps are also being fixed, and some of the streets in the neighbourhood of the railway station will probably soon have their gas lamps replaced by electric ones.

In Vesteras, Sweden, the gas company has recently erected a central electric station, of which a few particulars may be of interest. It is the first installation in Sweden on the Edison-Hopkinson three-wire system, and it is extended to the different parts of the comparatively small town. The engine house, which is located in the immediate neighbourhood of the gasworks, has a separate boiler room, with one boiler and room enough for another. The steam engine is a horizontal compound one of 55 effective horse-power, and here, too, there is room for extensions. The engine has two fly-wheels, which serve as pulleys, each working a Wenström dynamo, type *h*, each of 350 16-candle incandescent lamps capacity. Outside the engine house the main wires are directed to the different parts of the town, the town hall, the "Norrmalus" part, and the central district. All these main cables are on the three-wire system. The steam engine and the boiler are from Munkeell's Engineering Company at Eskilstuna, and the electric installation, which appears to be thoroughly well done, has been carried out by the Elektriska Aktiebalaget, Stockholm.

In Norway electric light has for the first time been used in diving operations and work under water. The occasion was some repairs on the brig "Vestalinden," and the electric light was supplied from on board the salvage steamer "Pluggen," where an electric installation, intended for use both above and under water, has recently been completed.

In Stockholm and the surrounding country the large Stockholm General Telephone Company and the State Telegraphs have for some time been at loggerheads, and unless a compromise be arrived at, the war is not unlikely to assume important dimensions. The question of the telephone tax gave the first occasion, and the State Telegraphs seem more and more determined to "get at" their opponent. The large State telephone line between Gothenburg and Stockholm is a direct blow against the Stockholm Telephone Company, which was contemplating the erection of a similar line, and which had already completed a telephone line part of the distance (Stockholm - Vesteras), with which the State telephone line is now parallel. The State Telegraphs then bethinking themselves of certain regulations interfering with the right of private individuals to erect poles on State land, the matter was looked into, and about one hundred of the Telephone Company's poles were found to have been placed on State land. Whether the State Telegraphs will compel the Telephone Company

Digitized by Google

to remove these poles, and whether the company can remove them without disturbing the whole line, remains to be seen. It is, however, possible, that the State Telegraphs may strike the Telephone Company still nearer home. The State Telegraphs have obtained by Government influence the right from the town of Stockholm, "before everybody else," to attach to the houses the lower supports for telephone wires. That it has the same right as far as the buildings of the State are concerned goes without saying. It remains doubtful how far the State Telegraphs will make use of this right; but so much is certain, that the State Telegraphs through this right can, if they choose, erect their own telephone system within the town, and that they in that case have preference before all others, whether already existing or future companies. This latter alternative is, however, one must presume, not very likely to become a reality.

CORRESPONDENCE.

THE MAGNETIC EFFECT OF CONVECTION AND DISPLACEMENT CURRENTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I notice in your issue of November 16th a suggestion from S. P. Thompson that it would be advisable for some one to repeat Prof. Rowland's convection experiments. Prof. Rowland himself desires to get more accurate measurements than were possible with his Berlin apparatus, and to that end has designed a new form for the experiment; this I have been working on for some time past.

In the new apparatus there are two gilded ebonite discs surrounded by guard rings, and revolving on horizontal axes; the lower element of an astatic system hangs midway between the discs, in the line of their centres.

The discs are run at about 100 to 130 revolutions per second, about double that attained in the old experiment; this higher speed, with higher electrification, will make the determination a more accurate one.

Although no measurements have yet been made, the quantitative effect is easily obtained. Deflections of about half a degree of arc are got by reversal of comparatively low electrification.

I may also add that experiments on the magnetic effect of displacement currents have been made at this laboratory. The deflections, as calculated from the dimensions of the apparatus, &c., were great enough to be observed with certainty; but the disturbing causes were so numerous and so great that the work has been given up for the present.—Yours, &c.,

CARY S. HUTCHINSON.

Physical Laboratory, Johns Hopkins University,
Baltimore, Md., December 3, 1888.

ELMORE'S ELECTRO-BURNISHING PROCESS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reply to your correspondent, M. Gaston Roux, I herewith supply an abstract of the results of a series of tests which have been made on the above wire, and which will, I hope, give the desired information:—

ABSTRACT OF RESULTS.

All at 0° Centigrade.

Size of wire.			Resistnce of 1 metre. Weighing 1 gramme.		Ratio of conductivity of annealed and hard wire.	Percentage conductivity relative to hard standard copper.	Density.	Mean elongation under breaking strain.
B.W.G.	Diameter in inches, approx.	Condition.	Hard.	Anneal'd				
			B.A. ohms.	B.A. ohms		Per cent		Pr ct.
12	0·113	hard	0·14337	—	—	102·46	8·343	2
		annealed	—	0·14072	101·89	—	8·939	—
14	0·0825	hard	0·14330	—	—	102·51	—	1½
		annealed	—	—	—	—	—	—
17	0·057	hard	0·14359	—	—	102·31	8·938	¾
		annealed	—	0·14069	102·06	—	—	—
18	0·049	hard	0·14366	—	102·21	102·26	—	¾
		hard	0·14357					
		annealed	—	0·14056	—	—	—	—
21	0·031	annealed	—	0·14061	—	—	—	—
General mean.....			0·14349	0·14065	102·01	102·38	—	—
Say.....			0·1435	0·1406	102·0	102·4	—	—

From the general mean above has been calculated the resistance of a wire in different units of length, weight and diameter, as under; all values at 0° C.:—

Resistance of a Wire in B.A. Ohms.

—	1 metre weighing 1 gramme	1 foot weighing 1 grain.	1 statute mile weighing 1 lb. (avoird.)	1 nautical mile (2029 yards) weighing 1 lb. (avoird.)	1 metre long and 1 millimetre in diameter.	1 foot long and $\frac{1}{1000}$ inch in diameter.	1 statute mile long and ·065" in diam. = No. 16 B.W.G.
Hard.	0·1435	0·2057	819·4	1089·0	0·02043	9·652	12·06
Annealed.	0·1406	0·2016	802·8	1067·0	0·02003	9·461	11·825

It will be seen from the above that the resistance at 0° C. of the hard drawn wire 1 metre long and 1 millimetre diameter is ·02043 B.A. ohms, and when annealed is ·02003 B.A. ohms. The corresponding values for so-called "pure," or, say, standard copper are ·02104 hard and ·02057 annealed (B.A. Reports). Hence the conductivity with respect to *volume* is 102·98 per cent. hard and 102·7 per cent. annealed.

The *specific resistance* of, say, the annealed wire in B.A. microhms is obtained thus—

$$\frac{\cdot02003 \times 10^6 \times \cdot7854}{10^4} = 1\cdot573 \text{ B.A. microhms.}$$

Otherwise thus—

Since 8·939 is the density of the metal, this number expresses the weight of 1 cubic centimetre; hence a bar 1 metre long and 1 square centimetre in section would weigh 893·9 grammes, and would have a resistance $\frac{1}{893\cdot9}$ of a wire the same length and weighing 1 gramme $= \frac{\cdot1406}{893\cdot9}$; hence a length of 1 centimetre of this bar would have a resistance of 1·573 B.A. microhms, as before.

I would also refer your correspondent to an article which appeared in your contemporary *Engineering* for November 23rd, 1888, pp. 509 and 510.—Yours, &c.,

December 11th, 1888. C. J. S.

ELECTRIC LIGHTING OF SCHOOLS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Will you allow an amateur, who began his experiments nearly half a century ago, and who has made the subject his "hobby" ever since, constructing his own apparatus, and assisting others, to write a few words on the above subject as carried out in the schools of Holy Trinity District, Eastbourne? I have always been deeply interested in electric lighting since, close on forty years ago, I helped a well-known Cheltenham amateur, now passed away, in producing an arc with 120 Smee cells, at the Shire Hall, Gloucester.

It is well known to many of your readers that our town of Eastbourne is somewhat in the van with regard to electric lighting, and perhaps to them and others it will be interesting to hear a few particulars of our company's doings since the new departure of having a central station near the railway terminus, under the able management of Mr. H. T. Harris and an excellent staff, with efficient workmen to carry out the details.

At this station any evening, and during winter from 6 to 8 a.m., is to be seen in full work an engine of 200 horse-power, making 92 revolutions per minute, driving one large alternating dynamo making 550 revolutions per minute.

From this centre two main cables distribute the current thus produced throughout the town—the furthest point reached represents nearly three miles of underground wires enclosed in iron pipes. This most distant house is a large ladies' school.

This alternating current of 2,000 volts is carried into any house or group of houses by a main brought into celler or outhouse, where is fixed the converter or transformer—a most important instrument designed to transform the 2,000 into a 100 volt current for use within. To those who do not know this instrument I may just mention that it consists of a large core of very soft laminated iron, surrounded by a primary coil of *fine* wire, the secondary coil being made of *stout* wire, the reverse of ordinary coils. The iron core becomes bathed or saturated with magnetism, and induces the comparatively low-tension current for lighting the incandescent lamps,

Digitized by Google

and can be arranged for any number. The next very important matter is that of *measuring* the current used. For this purpose a "Lowrie-Hall-Kolle" meter is used, the principle of which being the deposition of metallic copper (as in an ordinary cell) by a differential current of 4 volts produced by the introduction into the circuit of an accumulator. The deposit is comparatively slight, but when accurately weighed it shows exactly what has passed into the building. A matter of great importance to the public is that if this meter acts imperfectly the record is against the company, as *over deposit* cannot take place. The wires carry the current from the meter direct to the lamps through earthenware switches, safety fuses being used everywhere.

Our school premises comprise one large room 100ft. long by 24ft. wide, subdivided by movable partitions into four nearly square rooms, and another smaller room, 52ft. by 22ft., not divided, besides four good-sized class rooms. Each square room in the large building is lit by four 16-candle lamps, suspended from the beams near the corners, and one 32 in the centre. The smaller one has eight lamps of 16 candle-power hanging from beams at regular distances, while each class room has two. This gives a delicious mellow light; but if this were the only advantage our management would not have abolished gas in favour of electric lighting. *The* great advantage of the latter is, the air does not get vitiated by its use, vitiated not only by the consumption of oxygen and formation of carbonic acid, but by the introduction into the atmosphere of a very considerable variety and amount of deleterious chemical agents, which do much damage to health and property.

Take our schools as an example. We have over 600 children in attendance. At this time of the year towards 3:30 we must light up for an hour: the air is already vitiated, and brains begin to be fagged as a consequence. All at once 70 gas jets at least are alight, and each at a low computation consumes as much oxygen as six persons; the equivalent of *420 more* people is crowded in, whose breath—well, we will not say what they breathe out, chemists will tell us that.

With the new light all this is changed, and the last hour goes, not so easily as the first—that is impossible—but I hardly know how fitly to describe it.

I trust to see our church lighted with it ere long—one Eastbourne church is already—and I feel sure that very soon this will become *the light*, while our old friend gas, to whom we are grateful for past favours, will more and more take the place of coal for heating and cooking purposes.—Yours, &c.,

THOS. RYDER.

Holy Trinity Schools, Eastbourne, December 5, 1888.

THE GEYER-BRISTOL AMMETER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The ammeter described in your last issue under the above name is no doubt a very useful instrument for small currents, but I am afraid an upward limit would soon be reached. Some two years ago I tried some experiments with a similar idea, the compound strip being in my case composed of brass and iron coiled up into a flat spiral. To eliminate error due to air temperature two of these spirals were used; to one was attached the pointer and to the other the dial. So long as the two were at the same temperature there was no relative movement of the pointer on the scale. That is to say, both the pointer and dial moved together, and so kept in the same position with respect to one another. But on passing the current through the spiral carrying the pointer a deflection was obtained. This instrument was fairly satisfactory for small currents, though the time required for the indications to assume their correct and final value was somewhat large, varying with the current. On using the instrument for large currents, in addition to the increased time required to attain the maximum deflection for any current, another difficulty was observed in the shape of the leads growing proportionally hot for some considerable distance to and from the instrument. This difficulty will, I think, be experienced with all ammeters depending for their action on the heating of a part of the *main* circuit. To overcome this some experiments were next tried by me with an arrangement having the heated portion as a *shunt* to part of the main. Thus a length of 2ft. of the main was bent into a U-shape and shunted by about 1ft. of wire of small section relatively to the section of the main. The sag due to heating of this fine wire was observed directly on a small scale. This made a somewhat bulky instrument with very small scale, but was free from the other objections.—Yours, &c.,

SAM. JOYCE, JUN.

113, Richmond-road, Dalston, E., December 8th, 1888.

PROVISIONAL PROGRAMME OF THE INTERNATIONAL ELECTRICAL CONGRESS OF 1889.

The following is the programme which the Executive Committee propose to lay before the forthcoming International Congress of Electricians at Paris:—

FIRST SECTION.—MEASUREMENTS.

Units of measurement. Recent determinations of the unit of resistance. The ratio of the electro-magnetic to the electrostatic units. New names for practical units. Measuring instruments. Resistances. Alternating and continuous currents. Electromotive forces. Capacities. Coefficients of induction. Practical standards of current and E.M.F. The magnetic and electrical properties of metals.

SECOND SECTION.—DYNAMO MACHINES; MOTORS; ELECTRICAL DISTRIBUTION; TRANSFORMERS.

Recent progress in the theory and construction of dynamo machines. Different methods of calculating the data of a machine. Electro-magnetic armatures with iron cores. Electro-dynamic armatures without iron. Machines for lighting, transmission of power, generators and receivers, electrolysis. Output. Machines for distribution. Different methods of automatic regulation. Mechanical and electrical methods. Transmission of power. Mains. Central stations. Possibility of constructing very large machines. The employment of many small machines, or of a few large machines. The advantages of coupling machines in parallel or of running independently. Transformers. Alternating-current and continuous-current transformers; the two systems compared. Alternating-current transformers; their theory, improvement, efficiency. Different methods of distribution. Automatic regulation. Alternating-current dynamos and motors, compared with continuous-current machines. Discussion with regard to the machines and other apparatus used in continuous-current distribution and in alternating-current distribution by means of transformers.

THIRD SECTION.—ELECTRO-CHEMISTRY.

1. *Batteries and Accumulators.*—Practical value of the chief types employed; E.M.F.; output, durability, &c.

2. *Electrolysis.*—The E.M.Fs. necessary to decompose the ordinary iron compounds. The conditions necessary for a good deposit of the ordinary metals: copper, silver, gold, nickel, platinum, &c. Current densities, composition of baths, temperatures, &c., required for the various kinds of deposits.

3. *Electrometallurgy.*—Principal methods of separating and refining metals. The production of metals and alloys by electric furnaces.

FOURTH SECTION.—LIGHTING.

Respective values of arc and incandescent lighting. Advantages and disadvantages of high candle-power incandescent lamps. Methods to employ when running arc lamps in series or parallel, without rheostats between the lamps and the machines. Best methods of manufacturing incandescent lamps with a view to increasing their life and efficiency. Best methods of erecting and working central lighting stations.

FIFTH SECTION.—TELEGRAPHY AND TELEPHONY.

1. *Telegraphy.*—The employment of dynamo-electric machines. Underground wires, their employment, laying, and life. Telegraph lightning guards. Fast-speed transmitters: their working and employment. Multiplex apparatus.

2. *Telephony.*—Running wires; steel, bronze, hard-drawn copper, compound wires. Insulators. Joints. Posts and stays. The employment of overhead and underground wires. Dampers. Methods employed to overcome mutual induction. Metallic circuits. Simple or multiple switch-boards. The number of subscribers served by one operator; the number of connections which can be made by one operator in an hour; the time necessary to make a connection. Interior economy of exchanges. Rules for subscribers. The repair and maintenance of subscribers' instruments. Microphones. Batteries. Running several instruments on the same line. Statistics. Legislation. Development of the system. Tariffs. Automatic Posts. Interurban telephony.

3. *Various Applications.*—Electricity applied to railways, to civil engineering, to military and naval purposes, to clocks, to chronography.

SIXTH SECTION.—ELECTRO-PHYSIOLOGY.

Comparison of the effects obtained when using various kinds of electro-medical apparatus. The necessity for defining the currents employed in medicine and connecting them with the usual electrical units. The best methods of determining the exact nature of electric phenomena in animals. The effects of alternating and continuous currents on living beings. Electrolysis of the tissues. Dangers of electrical installations. The conductivity of organic bodies, especially that of the human body.

Digitized by Google

PARLIAMENTARY NOTICES UNDER THE ELECTRIC LIGHTING ACTS.

In addition to the Provisional Orders for which, as stated in our last issue, application will be made to the Board of Trade by the 21st inst., two others have to be noticed, which will be applied for by the Electrical Power Storage Company (Limited) and the House-to-House Electric Light Supply Company (Limited).

The Electrical Power Storage Company will ask for an Order (besides that which we have noticed relating to their proposed lighting in the parish of St. Martin's-in-the-Fields and the Strand District) authorising them to produce, store, and supply electricity in the Parish of Paddington. Among the streets, &c., in which it is more particularly proposed to place electric lines and works, are London-street, Devonport-street, Sussex-place, South Wharf-road, North Wharf-road, Harrow-road, Irongate Wharf-road, Praed-street, Cambridge-place, Market-street, Norfolk-square, Star-street, Sale-street, Edgware-road, Watling-street, Gloucester-square, Radnor-place, Somer's-place, Southwick-place, Grand Junction-road, Hyde Park-square, Albion-place, Chester-place, Hyde Park-gardens, Clarendon-place, Hyde Park-street, Albion-street, Upper Porchester-street, Cambridge-square, Southwick-crescent, Oxford-square, Norfolk-crescent, Burwood-place, Cambridge-street, Portsea-place, Upper Berkeley-street West, Berkeley-place, Connaught-square, Upper Seymour-street West, Connaught-place, Stanhope-place, Uxbridge-road, Gloucester-gardens, Porchester-mews, James-street West, Cleveland-gardens, Porchester-terrace, Leinster-gardens, Cleveland-square, Craven-hill, Lancaster-gate, Upper Hyde Park-gardens, Devonshire-terrace, Craven-terrace, Westbourne-terrace, James-street, Bishop's-road, Eastbourne-terrace, Craven-road, Charles-street, Spring-street, Westbourne-crescent, Sussex-square, Westbourne-street, Bishop's-road Bridge, Bishop's-road Station, Paddington Station, Praed-street Station, Talbot-square, Conduit-street, Delamere-street, Westbourne-terrace-road, Westbourne-terrace, Queen's-gardens, Gloucester-place, Gloucester-terrace, Lancaster street, and Stanhope-street.

The House-to-House Electric Light Supply Company (in addition to their intended application—noticed in our last issue—respecting the lighting of the parish of St. Mary Abbotts, Kensington) will ask for an Order empowering them to produce, store, and sell electricity in the Strand district. They notify that "the houses on both sides of every road or street in the area of supply are included within the area of supply."

LEGAL INTELLIGENCE.

Edison and Swan Electric Light Company v. Holland and Others.

THE CASE ON APPEAL.

The hearing of this case was resumed in the Court of Appeal, before the Lords Justices Cotton, Lindley and Bowen, on Thursday, December 6th, at 2 p.m.

Sir Richard Webster (the Attorney-General), Mr. Aston, Q.C., Mr. Moulton, Q.C., and Mr. Bremner appeared for the appellants; and Sir Horace Davey, Q.C., Mr. Finlay, Q.C., and Mr. J. C. Graham for the respondents.

Mr. MOULTON concluded his argument on behalf of the appellants. Thin weak carbon was enough in itself for the purpose of this patent without strengthening it with anything else. A mere filament would stand a terrific strain owing to high temperature.

LORD JUSTICE COTTON: Mr. Justice Kay relied on the fact that all the lamps that were sold were made under the improved methods.

Mr. MOULTON: A new type of lamp was not produced, and it is not necessary that the lamp should be a commercial success; and I contend that it is not a good legal objection to say that a patent is useless because another method is a better one.

LORD JUSTICE LINDLEY: That was settled in the musical instruments case.

Mr. MOULTON: And the same argument will apply in this case.

This concluded the case for the appellants, and that for the respondents was then opened.

Mr. FINLAY: I wish to show that the principle was not new and the processes were worthless, and if I make out either of these arguments, the patent fails. It has been suggested that we have infringed their process by forming a filament before carbonisation. Now we want to show that the design was not new. In the case of Woodhouse and Rawson there were four points of difference as compared with this case. The fourth point, which was of the most importance, was that in the former case the utility of the patent was admitted—that was not disputed. What we say in the present case is that we have not infringed the process claimed in this patent. The only attack made upon us before Mr. Justice Kay, and which the evidence will support, is the allegation that we have infringed the principle which is claimed by Mr. Edison in the second claim of this patent.

Mr. BREMNER: I do not admit that.

Mr. FINLAY: The claim was for the infringement of the principle, not for the infringement of the process.

Mr. BREMNER: The shaping before the carbonisation is admitted.

Mr. FINLAY: I apprehend that if the modes of carrying out the principle as described, or any of them, are insufficient, the patent will be bad. If a patentee took out a patent for a new principle and described six possible ways of carrying it out, and one of those modes was bad, the patent would be bad altogether. Now, we say in the first place that there is nothing new in the principle, and that in three points the process described has been proved to be insufficient. The secret history of this matter no doubt is that this patent, which was never heard of at the time it was brought out, was raked up for the purpose of making a monopoly in these lamps.

Mr. ASTON: It was carried on.

Mr. FINLAY: It has been admitted that no lamp was ever made under this patent except for purposes of litigation.

Mr. ASTON: No.

Mr. FINLAY: My friend grunts (a laugh), but that is the case. I do not think my friend can point to any evidence as to a single lamp having been made under this specification except for purposes of litigation. I challenge my friend to point out a single case.

Mr. ASTON: That is so with reference to cotton thread; but as to bamboo filament, there was abundant evidence that they were made so far back as 1881.

LORD JUSTICE COTTON: That was my impression.

Mr. FINLAY: These bamboo lamps were made under patent—

Mr. ASTON: I made a mistake. I should have said March, 1880, and not 1881.

Mr. FINLAY: I think my friend Mr. Aston is really under a misapprehension about this. Mr. Graham's recollection agrees with mine upon the point. Moreover, the witnesses who tried to make filaments out of tar putty and failed had not put to them in cross-examination the point on which their failure depends. It is clear, therefore, that those who were conducting the case then for the plaintiff company had not the least idea what the real essential point in this process was. Now as to the process of carbonisation. Of course it was known before the date of Edison's patent, but not the carbonisation of such a delicate structure as filament, but only for the purpose of making gunpowder, &c. The attack made is that the experiments were not fair experiments because the crucible used was porous; but the crucible used was an ordinary earthenware crucible, and I contend that there is no ground for attack on the witnesses on this point. What we say is that we have established that the description is insufficient and the process useless; and I apprehend it is enough for us to show on any one point that the description of a method given for carrying out the principle of a scheme is insufficient, and that if we do that the whole thing breaks down. I will now call attention to the evidence adduced in the case in the Court below, and I will deal with the question of fact, and not so much with the question of law.

LORD JUSTICE COTTON: You are entitled to argue, but I shall follow the view of the Court below.

Mr. FINLAY: There is a good deal of evidence which has not been brought before that Court at all. A question of novelty is a question of fact.

LORD JUSTICE COTTON: If you can give us evidence on the question of novelty you may proceed, but I thought you wished us to change our view as to the sufficiency of this specification.

Mr. FINLAY: I shall submit that there was a great deal of evidence not before the Court at all on this point—that there is really no novelty whatever in high resistance with regard to this particular lamp. We say there is no novelty. If the point of the process is that the carbon filament was formed before carbonisation that was not new, because it had been used in lamps made by Mr. Swan before the date of this patent. After reviewing the evidence of Sir Frederick Bramwell, Mr. Finlay added: We shall submit that this patent really had no appreciable effect whatever on electric light, although it has been claimed for it as having introduced the only commercially successful electric light. Prof. Stokes's report also shows that electric light, made even with the aid of all the information obtained up to the present day, could not, if carried out according to the specification of Mr. Edison, be commercially successful.

LORD JUSTICE BOWEN: Do you deny its utility?

Mr. FINLAY: I say that if there were no other electric light lamps at all these lamps would not be a success.

Mr. ASTON: Why not?

Mr. FINLAY: On account of their short duration. Then, again, the only lamps made by Mr. Gimingham were made out of lampblack and putty. He did not try any lamps made under any of the processes described in this specifiation; and that brings me to the end of the case as produced on behalf of the appellants. Amongst the grievances unfolded by the Attorney-General was one to the effect that they had not been allowed to bring the whole of their case before Mr. Justice Kay. Now, after the advantages enjoyed by Mr. Aston I cannot understand this grievance of his learned leader. I propose to call attention to certain portions of the evidence given on behalf of the defendants in the action. I think it necessary to read enough of the evidence given by our witnesses to show that they really did try to make conductors by processes mentioned in Mr. Edison's specification. I will also direct your lordships' attention to the cross-examination of those witnesses, and ask you to make the necessary inference in favour of the respondents. Undoubtedly a great amount of detail will be saved by reading the report of Prof. Stokes.

At this stage the Court adjourned.

The case was resumed on Friday morning.

Mr. FINLAY: This outburst of activity in incandescent light did not take place until considerably after the patent now in question, as I will show by the evidence.

LORD JUSTICE COTTON: I thought you were going to raise the question of novelty.

Mr. FINLAY: Certainly.

LORD JUSTICE COTTON: Will you not take that first?

Mr. FINLAY: I thought I would establish the point I have mentioned. What we shall show is this—that the first exhibition of Edison lamps in Europe was in Paris in 1881, and the first exhibition in England was in the autumn of 1882 at the Crystal Palace. With these exceptions

Digitized by Google

the only evidence as to any Edison lamps having been seen by witnesses relates to six lamps referred to by witnesses which were not made under this patent, but under the patent of November, 1879. I mention that as an important point, which can be supported by evidence.

LORD JUSTICE BOWEN: We should like to have a list of the experiments which have been conducted, and which have proved to be failures.

Mr. FINLAY: I will have the list made out, my lord. Now, we say that the process as conducted by us at our works would not be an infringement of any of the processes in Mr. Edison's patent.

Mr. ASTON: We contend that you have infringed.

Mr. FINLAY: We work up the tar putty for such a length of time and with so much force that it makes the necessary filament and is very different from what it was before.

After reading a body of evidence on the question of manufacture, Mr. FINLAY added: The cross-examination by Mr. Aston and other counsel for the appellants does not contain a hint as to the necessity of going on with the working up of the tar putty for the length of time, and with the expenditure of force which has been found necessary and which makes all the difference between failure and success. At that time the plaintiff company did not know how to make up filaments from this tar putty, and yet I suppose their counsel was put in possession of all the information they had upon that point.

Mr. ASTON: We brought the filament into court. We actually did it, and knew how to prepare it.

Mr. FINLAY: Then you kept it to yourself, because there was not a hint about it in court.

Mr. ASTON: There was not a point made of it on the other side.

Mr. FINLAY: Oh! Now the secret consists of going on for a hour and a-half after the putty has become homogeneous, so that with great force filaments can be formed. I think my friend Mr. Aston, in saying he knew that at the time, was imagining (a laugh). He would have let it out had he known it (laughter). Then as to the cross-examination of the witnesses as to the directions in the specifications being sufficient to make a practically useful lamp, it is idle to suggest that while the directions are not sufficient, they may be supplemented by something else in another patent or by scientific knowledge now possessed with regard to the filament.

LORD JUSTICE LINDLEY: If you confined yourself too rigidly to the specification, I suppose you could make nothing out of it.

Mr. FINLAY: Of course knowledge is required.

LORD JUSTICE LINDLEY: Of course with a certain amount of skill and a certain amount of desire to succeed.

Mr. FINLAY: If I was told to chew I should do it, and do it thoroughly (laughter). Take, for instance, the case of the tar putty. How could it have been known that it was necessary to go on after it was tar putty. The secret of failure is now known, but it is not a thing that even a scientific man could possibly know. We produced five or six scientific witnesses who all tried to deal with this tar putty and failed, and it was never suggested until Prof. Stokes' experiments what the secret of success was. We cast about in all directions, but it was not revealed till after Prof. Stokes' report, and we then found that the thick putty could be made into the necessary consistency for filaments, after the exercise of great force, at the end of a certain time.

LORD JUSTICE LINDLEY: Have samples of the failures in working up the thick putty been produced?

LORD JUSTICE BOWEN: I am not aware that such samples have been produced.

Mr. ASTON: My friend Mr. Finlay's statement as to the change in the character of the tar putty is not borne out.

Mr. FINLAY: I contend that my friend, Mr. Aston, did not cross-examine about the character of the putty or of the nature of the crucible used. As a matter of fact, too, the lamp F J B 1 never broke down. (Mr. Aston dissented). My friend shrugs his shoulders (a laugh). The electric light was turned off.

LORD JUSTICE BOWEN: But it smoked.

Mr. FINLAY: If it did it was very slightly.

LORD JUSTICE LINDLEY: There was smoke on the glass.

Further reviewing the evidence Mr. FINLAY added: Mr. Justice Kay referred to the fact that, in his judgment, at that time there was no industry for making filaments; there was no class of workmen for the purpose.

LORD JUSTICE BOWEN: Would an ordinary chemist have understood the process?

Mr. FINLAY: I do not think an ordinary chemist would do it. I submit it is conclusive on this point. How could a man have known that in working out this specification, after the application of great force and a certain expenditure of time, the necessary filament could be obtained from the thick putty? The appellants themselves did not know the secret until after a series of laborious experiments performed for the purpose of winning this case.

Alluding to two experiments referred to in the evidence as "Tar putty A" and "Tar putty B," Mr. FINLAY said: The difference between the two was the addition of a little lampblack before it came to the required consistency.

Mr. ASTON: No reference was made to the last addition of lampblack before.

Mr. FINLAY: Then on the question of the admixture of oxide of zinc with the tar putty, I do not know what is the suggestion of my friends on the other side as to the flaw in these experiments. They do not use, as Mr. Justice Kay said, the proportion of oxide of zinc required.

LORD JUSTICE COTTON: If we are to go into an infinite number of issues we shall never get through it.

LORD JUSTICE BOWEN: I did not know we were going into this question of oxide of zinc.

Mr. FINLAY: Then as to the question of non-conducting, non-carbonisable substance, it cannot be said that we have coated the conductor with one-third of its size, because we have merely "dusted" it with asbestos.

LORD JUSTICE LINDLEY: What you say is that "dusting" is not "coating?"

Mr. FINLAY: That is so.

LORD JUSTICE COTTON: If we go on like this we shall not finish till some time after Christmas (laughter.)

Mr. FINLAY (after reading some further evidence): We approve of Mr. Sellon's experiments as well as Dr. Tidy's, which had been made quite apart from Mr. Crookes's.

The ATTORNEY-GENERAL: The question is whether the infringing lamp was made in accordance with the latest specification. I hope your lordships will watch the evidence on this point.

Sir HORACE DAVEY: We intend to rely upon that.

Mr. FINLAY: We have challenged over and over again the appellants to say that lamps were made after the pattern of 1879, except for trials, and they failed to do so. We say that no single commercial lamp was made under that pattern, that there was insufficiency and want of utility in those which were made.

At this stage it was agreed that Sir HORACE DAVEY should address the Court on behalf of the respondents. He said: The Attorney-General, in the course of his speech, referred more than once to the fact that I was leading counsel for Woodhouse and Rawson.

LORD JUSTICE COTTON: It will not make the slightest impression upon us.

Sir HORACE DAVEY: I must now ask your lordships not to be influenced by the evidence in the previous hearing, but to give full consideration to that which we now put before you and the new points we have raised. Now, the second claim is framed in language which includes the combination of the parts, including filaments made not only in the manner prescribed in the specification, but in any conceivable manner in which filaments could be made. The question which comes before you, in a different form and under different materials, is what is a filament within the meaning of Edison's specification, and how does it affect the former judgment?

The case was here adjourned.

SATURDAY, DECEMBER 8.

Sir HORACE DAVEY continued his addressed on Saturday morning. He said: We have brought before your lordships a body of evidence—cogent evidence—as to the wholly insufficient direction contained in the specifications to enable any person to make a successful lamp. We have established this remarkable fact, that no single lamp is known to have been made by Mr. Edison, or anybody else, in accordance with the specifications, without the addition of the directions. I have looked through the evidence again, and although my friends on the other side were challenged to produce a lamp so made no evidence as to such a lamp having been made was produced. A lamp was certainly handed up to the Court, and we were told that it was made in accordance with Mr. Edison's specifications; but that is now known to contain other elements, and to have been made not exclusively according to the directions of the patent of November, 1879, but according to those of subsequent patents. If the second claim has the wide signification which the witnesses give to it, it fills the whole field of incandescent lamps. In the present case the filament is made in a totally different manner from that described in the specification, and we say that no lamp is known to have been made exclusively from the directions contained in the specification of 1879. On this point the case comes before you in a totally different aspect. The second claim covers all incandescent lamps which contained a filament, however made and of whatever resistance. Now I reserve to myself to question the correctness of this claim; I do not abandon it on the part of my clients. In order to protect a principle you must first have discovered the principle, or the principle must be new; secondly, the modes of carrying it into effect must be sufficiently described, and produce a certain practical result. We contend on these points that the principle is not new, as shown by the evidence of Mr. Swan and other witnesses; and that although Mr. Edison supposed he was the discoverer of the principle, the modes described in the specification are insufficiently given, and do not produce practical or successful results. We dispute Mr. Edison's claim to have discovered the idea, and to have a monopoly of all lamps which come within the idea; and we say that Mr. Edison's patent of November, 1879, was nothing more than a statement of an idea with a few crude and imperfect suggestions for carrying that idea into effect. That is our view, and we hope to make it good. Now a good deal of comment has been made on the words "commercial value"; but they were used by Sir Frederick Bramwell, and when he was cross-examined with regard to them he took refuge in generalities. With regard to the word filament, it is evident that its real meaning was not known at the time of this patent. If you look at the specification you will find that it includes such things as "wires" and "strips of paper," but there is no such definition or delimitation of "filament" as would satisfy the undoubted requirements of the patent law by particularly showing the nature of the invention.

LORD JUSTICE BOWEN: I do not know how far we are bound by the previous decision.

Sir HORACE DAVEY: Supposing that case was inefficiently argued on that occasion?

LORD JUSTICE BOWEN: Is this a question of law or of fact?

Sir HORACE DAVEY: I should think it is a question of fact.

LORD JUSTICE COTTON: A material fact has been brought out—namely, as to the formation of the "pencil," as it is called, before carbonisation. But I do not at present see that anything has been brought forward to show what "filament" really is.

LORD JUSTICE LINDLEY: I think this question of whether or not it has been sufficiently described is the most important in the whole case.

Digitized by Google

Sir HORACE DAVEY: I admit that so far as Mr. Swan was concerned the principle was known to him; but what was wanted was, knowledge of the way in which to carry it into effect by perfecting the details. I will now point out that in the case given in Webster of Turner and Winter it is laid down that if a patent is insufficiently described, or if there is ambiguity in the specification, the patent is void. The question in this case is, whether the nature of the invention is sufficiently described, so as to protect it—in other words, What was the meaning of the word filament, as used in the claim? Dr. Hopkinson has stated that the exact meaning cannot be given; but we say that it must be given for the purpose of this case. The suggestion made by Mr. Edison is that you should have a carbon conductor; that it should be as homogeneous as possible; and that you should get your resistance by increasing the length of your filament. I refer to that as showing that small sectional area was by no means a necessary element, and I submit there is not sufficient definition of the sense or meaning of the word filament in the second claim, and that the lamp F J B 1 was in anticipation of that claim. The fact is, it was not known that it was necessary to go on working up the tar putty until it acquired a particular consistency more resembling gutta-percha.

Mr. MOULTON: That is nonsense; there is not a particle of evidence about that.

Sir HORACE DAVEY: I am not going beyond Prof. Stokes's report. It was not till after that report that the witnesses knew how to make the filament, in regard to which Mr. Edison's specifications in his patent were insufficient. The same thing may be said with regard to the crucible, and the coating that was required for the conductor. The directions were, in fact, crude and insufficient, in exactly those points which Mr. Edison described as recent discoveries in his new patent. These are the points upon which we rely, and upon which we hope your lordships will decide in our favour.

The Court was then further adjourned.

(The remainder of this report will appear in our next issue.)

THURSDAY EVENING.

The ATTORNEY-GENERAL concluded his address this afternoon, having described the experiments carried out for Mr. Justice Kay's information as not having been made in accordance with the instructions contained in the specification as far as the tar putty was concerned, especially as to the kneading process. If their lordships' judgment was in his favour, he should ask to be heard as to the terms of the order.

Their lordships reserved their judgment, arrangements having been made for them to have access to the exhibits.

King, Brown and Co. v. The Anglo-American Brush E'ectric Light Corporation.

WEDNESDAY, DEC. 5.

The defenders' case was resumed to-day before Lord Trayner. His lordship intimated that he would give Thursday and Friday for the proof, but that it must finish on Friday. The Dean of Faculty indicated that it would finish on Friday.

The cross-examination of Prof. S. P. Thompson was resumed by Mr. Graham Murray. *Q.* In your examination-in-chief you said that Varley's first claim was not a claim for a machine, but for a principle, or rather an arrangement for cutting out the bobbins?—*A.* I rather meant the principle as embodied in the arrangement. In his examination he gave several illustrations of what he considered electrical absurdities in Varley's specification. *Q.* Am I right in saying that they are really all a sequel in your view of what you consider an erroneous statement at the top of page 7?—*A.* One of them is not, and of course such as it was, the machine worked irrespective of anything in construction. *Q.* Is it not the case that the machine disclosed in Varley's specification is a workable dynamo machine?—*A.* Yes. *Q.* I suppose you would say it was a good machine?—*A.* I do not know that any at that time could be much better. *Q.* What he does to insulate the bobbins is that at the neutral point he cuts them out of circuit?—*A.* Yes. *Q.* His arrangement shows that?—*A.* Yes. *Q.* That is precisely the same thing that is otherwise done by Haddan in his specification?—*A.* Yes, in a different way. *Q.* Varley said, "Part of the electricity developed by the machine is diverted to maintain the magnetism of the soft-iron magnets, and the remaining portion goes to produce the electric light." You said that passage was not consistent with the series-shunt arrangement?—*A.* Yes. *Q.* Take the first of the two sentences. "Part of the electricity developed by the machine is devoted to maintain the magnetism of the soft-iron magnets." That, I suppose, is consistent with a shunt arrangement?—*A.* It would lead me to think not. *Q.* Is it not true to say "that part of the electricity developed by the machine is diverted to maintain the magnetism"?—*A.* That is true. *Q.* And therefore consistent with a shunt arrangement?—*A.* Yes, so far. *Q.* Is it not also true, speaking of the shunt part of a series-shunt machine?—*A.* Yes. *Q.* Suppose a series-shunt machine, substitute for the first sentence these words, "Part of the electricity is devoted to the shunt." Now is it not true of the series-shunt machine to say that the remaining portion is used to produce the electric light?—*A.* Making that a substitute, it is quite true.—*Q.* How do you reconcile that with your former answer that the sentence was inconsistent with the series-shunt arrangement?—*A.* Because he should then have to read the last sentence as follows:—"The remaining portion is not only used to produce the electric light but to maintain the magnetism of the magnets." *Q.* Reading in the words you say, the current which produced the electric light and maintains the magnetism of the magnets cannot be in any sense said to be diverted?—*A.* No. *Q.* At lines 45 and 46 it says, "The greater portion of the electricity passes through the circuit of larger resistance, maintaining the magnetism of the magnets, and producing the light." Does not that give you the very condition you desiderate?—*A.* It gives me what does not exist in the first sentence, and that was one of the inconsistencies that puzzled me.

LORD TRAYNER: Does it supply you with what is wanting in the first sentence to make it consistent with a series-shunt?—*A.* Yes.

Q. Suppose the first sentence read, "Part of the electricity developed by the machine is devoted to maintain the magnetism of the soft-iron magnets, and the remaining portion is used to produce the electric light passing through the circuit of less resistance, which I term the electric-light circuit, maintaining the magnetism of the magnets and producing the electric light," would that have been consistent with a series-shunt arrangement?—*A.* It would. *Q.* What you call inconsistency reduces itself to this, that you find in two sentences what you expected to find in one?—*A.* I think it does. *Q.* Is the "diverting" of the electricity to maintain the magnetism of the magnets consistent with the principle of bifurcation?—*A.* In the language of that day I do not think it would have suggested it. *Q.* Can you suggest any operation to which the word "divert" is so appropriate as the operation of bifurcation?—*A.* Yes. *Q.* What?—*A.* I understand it is not that portion of the circuit current that is bifurcation, but the portion of the electricity in the machine. *Q.* And it is more appropriate to divert the current which is not going into one continued existence rather than taking the portion of the current which has assumed a continuity of existence?—*A.* Yes. *Q.* Haddan, in his specification, said, "I attain my object by devoting from external work a portion of the current in the machine and using it either alone or in connection with the current that works the field-magnets?—*A.* Yes. *Q.* He is describing bifurcation?—*A.* Yes, by diverting part of a current. *Q.* You have been particularly careful to tell us that in Varley's specification you read "electricity" as meaning "current," and not as meaning electric force?—*A.* As electrical currents.

LORD TRAYNER: Take Varley's specification and read, "Part of the electricity," as part of the electric current, developed by the machine, &c.; what does diversion mean? Would it be inconsistent language to describe bifurcation?—*A.* It would not be the usual language, but it would be consistent.

Q. At line 38 of Varley, does electricity mean electric current or electric energy?—*A.* Electricity of the currents.

LORD TRAYNER: If it is not electric current produced in the machine, and not electric energy, what is it?—*A.* Electricity of the currents. I understand he is referring to the armature, which had more coils than one upon it. He would, therefore, have no current, but currents, and divert part of the electricity to go round the field-magnets.

Q. If it is part of the electricity which is diverted, and the thing which is diverted be current, do you not divert the current?—*A.* You divert part of the current. *Q.* The diverted part is in itself a current?—*A.* Yes.

LORD TRAYNER: The machine produced several currents, some for one purpose and some for another, whereas bifurcation is the production of a current at a certain point?—*A.* Yes.

Q. You said the principle of bifurcation was not a thing known to any electric workman; would he know that principle if he happened to know Wheatstone's machine?—*A.* Wheatstone's was a series machine adapted for shunt. *Q.* If a workman happened to know Wheatstone's shunt machine, he would know the principle of bifurcation?—*A.* I cannot answer that. *Q.* Well, Wheatstone's machine arranged in shunt?—*A.* Yes. *Q.* In the same way, if a workman happened to know Clark's patent he would there find the principle of bifurcation?—*A.* Yes; bifurcation was quite common in telegraphy. It was a very simple thing. *Q.* Varley at p. 8 said: "There are several well-known ways of doing this; but the method I prefer is to wrap the soft-iron magnets with two insulated wires, one having a larger resistance than the other." The soft-iron magnets then are field-magnets?—*A.* Yes. *Q.* Is not the idea of field-magnets wrapped with two circuits of wire quite inconsistent with Ladd, Ruhmkorff, and Wilde?—*A.* No. *Q.* Is it not the case that in these three machines the field-magnets are only wrapped with one wire and not with two?—*A.* Yes; but there was an extra wire. There were no drawings in Varley's specification showing the two windings. Taking Varley's commutator, that was inconsistent with separate excitation within the machine. *Q.* Take the passage on p. 8 at line 38, does bifurcation and separate armature excitation exhaust the total possibilities of the machine there described?—*A.* I think I may answer yes. *Q.* If you make a machine, and follow the directions given upon page 8, at line 19, you have told me that that excludes the idea of separate armature excitation—is there anything left except the idea of bifurcation?—*A.* The only possibility is absolutely separate excitation: that was not hinted at. *Q.* Is bifurcation the only remaining idea that is hinted at?—*A.* Bifurcation is not hinted at. *Q.* Can you point to any part of the specification which shows separate armature excitation?—*A.* The only passage is the passage referred to in the previous specification, which had separate armature excitation. *Q.* Are Figs. 3, 5, and 6 inconsistent with separate armature excitation?—*A.* I do not think so. *Q.* Why not?—*A.* Because there is nothing whatever to show how the wires were united to the group of commutators. *Q.* The connections are shown?—*A.* The connection between the bobbins is shown in groups, but nothing further. *Q.* There is nothing to suggest separate excitation?—*A.* There is nothing to suggest how it is to be done at all. Figure 17 in Varley's specification was a series-excitation machine pure and simple, and was of course inconsistent with separate armature excitation. *Q.* You said that a workman at the present day accustomed to machines now in use would read Varley's patent as describing a series-shunt machine?—*A.* Yes. *Q.* Can you reconcile that with your language that the words are inconsistent with a series-shunt machine?—*A.* Yes, because the workman would read the knowledge of the present day into it. Varley had a circuit of greater resistance, which he described as always closed, and according to the idea of the patentee that circuit was always to be kept

Digitized by Google

closed; and he put in the circuit the motor of a lamp. *Q.* If you were told, as a matter of fact, that Varley's machine was worked with an arc lamp (the Serrin), and that it was noticed that when the lamp was burning the magnetism of the machine greatly increased, what would that indicate?—*A.* That there was a coil in the circuit of the magnets; in other words, that the machine was at least series-wound. *Q.* If you were also told that when the lamp was out there was still magnetism in the magnets, as evinced by the sparking of the brush, what would that indicate?—*A.* One of three things. First, that there was residual magnetism; second, that there was excitation from some separate source; or, third, that there was shunt-winding. If the lamp motor was to be worked by the electricity in the machine it must be in the series; because, if the contact was made at one of the pulleys the circuit would be opened and the motor would cease. These disadvantages were got over by the arrangement of series-shunt used with the lamp. They then got the motor always working the shunt, which was not liable to be interrupted, and the magnetism maintained in order to supply the series which gave the lamp light. When the lamp went out the motor would begin to work bad, and when the lamp went on the motor would stop working. *Q.* Is not the series-shunt arrangement the best that can be devised for working that particular lamp?—*A.* Taking the commutator of Varley's machine, the segments were riveted on. *Q.* Could the wearing segments be easily taken off?—*A.* That would depend upon the state of the machine and the appliances in hand.

LORD TRAYNER: You could not do it with a quill pen (laughter)?—*A.* No, nor with a screw driver.

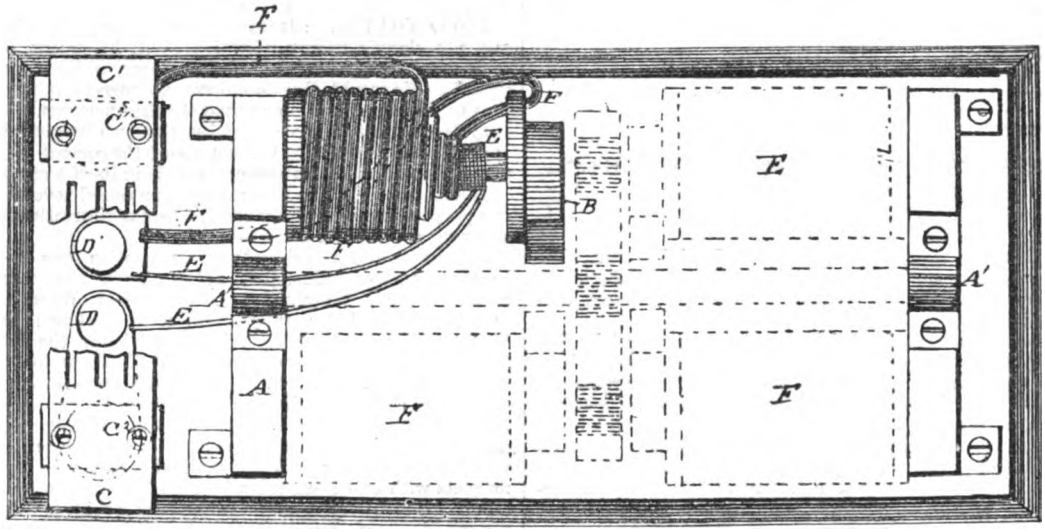
Re-examined by the DEAN of FACULTY: The series-shunt arrangement was preferable to any improvement on the shunt, and Brush indicated that in his specification. *Q.* How is speed reached in the most perfect series-shunt machine now in use?—*A.* It was calculated beforehand, but if you had a machine of a different size you would make a simple trial to reach the amount of speed with a view to maintaining constant potential. A passage in Varley's specification at page 7 provides for separate armature excitation in the case of the number of bobbins being in excess.

Prof. JOHN PERRY, Professor of Applied Mathematical Engineering at the City and Guilds of London Technical College, Finsbury, deposed that he had studied Haddan's specifications and relative drawings with the witness's view of the utility of the series-shunt machine. Both long and short shunt were quite clearly described in the drawings. The description of series-shunt winding was particularly clear, and was fully illustrated by the drawings.

Lord TRAYNER: I do not think there is any question as to the sufficiency of the description in Brush's specification. As I understand it, the question is whether Varley anticipated Brush's description by a disclosure of a shunt machine, and whether the defenders' patent is a new invention.

Mr. GRAHAM MURRAY: The defenders say that one reason why they cannot construe Varley's specification is that he gives no indication of constant potential. I retort that neither does Brush.

Examination continued: Since the date of Brush's specification nothing had been added to what Brush told them in his specification, except that alterations had been made in the dimensions and proportions of different sizes and varieties of dynamo machines. He did not think it possible to draw out a specification to give instructions for making a constant potential machine. Even at the present date, unless he was simply repeating an old machine on the same lines, he would require a certain amount of trial and measurement in order to get an approximation of constant potential. *Q.* Have you examined Brush's specification in order to ascertain whether he describes bifurcation as the method by which he divides his current?—*A.* Yes; and it is quite clear. *Q.* And the drawings absolutely exclude excitation from a separate source internally or externally?—*A.* Yes. He had read Varley's various specifications and the communication made by Prof. Wheatstone to the Royal Society. Wheatstone converted a series machine into what was now known as a shunt machine. *Q.* Did his communication, so far as you know, lead to the manufacture of a single shunt machine?—*A.* No. *Q.* Did it add to the knowledge of electricians in the slightest?—*A.* No. The idea was not put into any practical or useful form, but was a mere suggestion which required to be worked out. *Q.* As a matter of fact, did eminent scientific men so late as 1879 indicate ignorance of Wheatstone's suggestion?—*A.* Yes. Witness never heard of any machine being made according to Clarke's specification. Brush himself was one of the cleverest electricians, and he certainly did not know of it. It was not claimed in his patent. *Q.* In 1876 was there any machine likely to be known to workmen where electricity was divided, except Wilde's, Ladd's



Facsimile copy of Drawing in Haddan's Specification of Brush's Dynamo.

view of giving an opinion as the objections to the utility and the novelty of the invention, and the efficiency of the description in the specification. At the date of Brush's patent there were in use four kinds of dynamo machines—permanent-magnet machines; machines excited from a separate source; series-wound machines; and machines excited by a separate armature or otherwise, from a separate source within the machine. The witness then described the defects of series-shunt and separately excited machines as regards constancy of potential, and explained how these were obviated by compound winding. *Q.* Was that a valuable improvement? *A.* Exceedingly valuable. *Q.* Did Brush purport in his patent to give directions for preparing an absolutely constant potential?—*A.* He does not mention potential at all. The word was not known to electricians or common workmen at that date. What he wanted was a fairly good potential. The approach to constant potential was necessarily a matter of degree. *Q.* Did Brush's invention really supply the means of producing the compensating effect which tends to constant potential in a greater or less degree?—*A.* Yes. *Q.* Does the utility of the series-shunt winding necessarily depend on securing constant potential? *A.* No; its utility begins to be displayed whenever there are two wires compensating one another. Since the date of Brush's patent electroplating had been practised both with the shunt and the series-shunt arrangement. For electroplating the series-shunt arrangement was the most advantageous. It kept the potential constant whether they were plating one spoon or a hundred. That result was not obtained in the same degree with the shunt arrangement. For practical purposes the danger of reversal of polarity was slightly greater in the series-shunt than in the shunt machine. The instance which Mr. Brown had given of a reversal of polarity in a machine in his workshop did not militate against and Ruhmkorff's machines?—*A.* I do not believe there were any. In Varley's specification of 1876 he found no disclosure of the series-shunt arrangements. *Q.* What do you take to be the essential characteristics of the series-shunt arrangement?—*A.* Firstly, the whole of the electricity generated is employed at all times to maintain the magnets; secondly, the electricity divides itself between two circuits, two windings of the magnet; and, thirdly, in its method of division there is a current bifurcated. *Q.* What do you say of the first sentence in Varley's specification?—*A.* He speaks there of part of the electricity developing the machine and the other part being used for the electric light. That is inconsistent with the series-shunt arrangement. The specification certainly excludes any idea of bifurcation. The idea of a shunt was not at all well known then, and the only method was not by bifurcation. *Q.* Taking the passage as a whole, is there any part of it which appears to you to disclose the series-shunt arrangement?—*A.* If it had been written in the present day I should have thought that the latter part disclosed it. The first sentence is quite inconsistent with all that follows. The whole passage is perfectly consistent with separate excitation, and bifurcation is not mentioned. In one place he spoke of two distinct circuits, which was against any idea of bifurcation. It pointed towards an improvement of the Wilde arrangement, or of his own idea of 1867, to which he referred. *Q.* Is your view confirmed by a reference to Varley's previous patent of 1867?—*A.* Yes. He there describes two windings, one coming from a separate portion of the armature. *Q.* Is Varley's specification intelligible as a whole, or is it likely to puzzle or mislead any electrician?—*A.* It is very misleading, and there are many absurdities in it. He had examined Varley's machine, No. 29 of productions. From the number of binding screws on the machine he would say that it was constructed for

Digitized by Google

experiments rather than for work. These screws would allow it to be coupled up in almost any way, and could be used as a shunt or a series machine, or as a double-shunt machine. It could also be coupled up as a series-shunt machine.

LORD TRAYNER: It seems to be a very remarkable machine. It can be made to do anything (laughter).

Examination continued: He had examined the models produced by pursuers as being made in accordance with Varley's machine. The one shown him differed in many respects from Varley's patent. Varley's machine required a complicated commutator to work the cutting-out arrangement, and none of the models showed that the excellence in the mechanical construction of the Brush commutator and machine contributed largely to their success. He had examined the commutators of Wilde and Varley, and they did not appear to him at all to anticipate the Brush commutator.

Cross-examined by Mr. GRAHAM MURRAY: Siemens' communication to the Royal Society in 1880 did not give witness the impression that he treated shunt winding as a thing already known. He startled everybody. Every book since 1882 mentioned Wheatstone as the discoverer of shunt. The word "electricity" in a portion of Varley's specification might mean current. The word "divert" might be an appropriate form of expressing bifurcation. *Q.* A machine made according to Varley's specification would, as you say, not be capable of self-excitation, nor with a pure series winding. Would you please tell me what, then, is left except series-shunt?—*A.* For a machine so constructed nowadays we would say it must be a series-shunt, but I do not know what might be said at that time.

The cross-examination of witness was not concluded when the Court rose for the day, to resume on Thursday.

THURSDAY, DECEMBER 6.

Evidence for the defenders was resumed to-day before Lord Trayner.

Prof. JOHN PERRY'S cross-examination was continued by Mr. GRAHAM MURRAY: Varley's machine made by Siebe and Gorman, as it stood, could not be used as a series-shunt machine, but it could be connected up to be so used. It would be a perfectly natural way now of connecting that machine.

Re-examined.—With reference to the word "divert" in Varley's specification, the meaning which he thought a workman would have attached to it in 1876 would be to divert the electricity. He would have taken the idea of separate-circuit excitation, and not bifurcation. *Q.* Is it part of your objection to Varley's specification as a prior disclosure that it would form a puzzle to any electrical workman seeking to construe it?—*A.* Yes. *Q.* What, in your view, would be the arrangement which would make the nearest approach to a reconciliation of all the different passages?—*A.* I think separate-circuit excitation.

ALFRED HICKS, overseer of the *Graphic* Illustrated Newspaper Company's electrotyping foundry, deposed that the dynamo purchased by that firm from the Anglo-American Brush Company in 1883 had been put to work upon electrotyping, and during the five years there had been no difficulty due to the reversal of the poles of the machine. It had always worked satisfactorily.

Sir WM. THOMSON deposed that in his opinion the Brush series shunt-winding arrangement was a marked and valuable improvement upon previous arrangements. In particular, it was a valuable improvement upon the shunt and upon the series. The description in Brush's specification was such as would enable an ordinary workman to obtain the benefits of the invention without any difficulty. At the date of the Brush patent he did not think the shunt arrangement was known in practice; because he heard it first in consequence of Dr. Siemens's communication about 1879. He believed he himself had the first practical shunt machine for electric lighting; he got the machine from Dr. Siemens with some difficulty. He did not know of the shunt arrangement till 1879. He believed the series arrangement was in common use in 1876, and he knew it was in 1880. The arrangement in which the electricity was obtained from a separate source within the machine was in common use in 1876. That was an arrangement of which Wilde's machine might be taken as a type. He believed that what was now called compound winding was not known at all, even to scientific men, in 1876. Taking a passage in Varley's specification, he did not think that any electrical workman in 1876, reading that passage, would have had disclosed to him the system of series-shunt winding. The specification would have puzzled him. The puzzles were precisely such as would be apt to mislead an ordinary workman. For example, take the first sentence: "A part of the electricity developed by the machine is diverted to maintain the magnetism of the soft-iron magnets." He did not think it quite clear how the part was to be obtained. The workman of that time would consider how he was to get a part of the electricity and divert it from the desired external work of the machine, to sustain the power of the magnets. Then he said, "the remaining portion is used to produce the electric light." If it was divided into two parts in some way that would be clear enough, provided the remaining portion was used simply to produce the electric light; but the reader was led off the idea that the remaining portion contributed in any way to the magnetism of the magnets. Part was diverted to maintain the magnetism of the magnets, and the remaining portion was used to produce the electric light, so that the reader would be led to understand that it was used only to produce the electric light. Then he said, "There are several well-known ways of doing this, but the method I prefer is to wrap the soft-iron magnets with two insulated wires, one having a larger resistance than the other." That was not the way of doing that which was specified in the first sentence, and so the reader became very much puzzled. A new idea seemed introduced there inconsistent with the first sentence. Then he went on to say "The circuit of larger resistance was always closed, and the circuit of less resistance is used for the electric light." These words certainly would imply to the reader then—and, he thought, to the reader now—taking these words, and not thinking of compound winding, which he knows from subsequent disclosures—they would imply two circuits, the one a complete circuit of larger resistance which was always closed, and another distinct circuit of less resistance which was used for the electric light. When he spoke of two complete circuits, he meant two separate circuits. If there was to be electricity given through each circuit, there must be a source for each circuit. *Q.* By two separate sources, and not one source bifurcated?—*A.* Yes; I think the natural interpretation is two separate sources, and not two branches of one. The proper words for bifurcation would be a branch of less resistance, and not a circuit. [Shown Varley's machine made by Siebe and Gorman.] He observed that that machine had twelve terminals and a number of loose wires, and he saw that there were both thick and thin wires on the same magnets. It appeared to him to be an experimental machine, and one reason for that was the unusual number of terminals and loose wires, which permitted of various methods of coupling-up being tried. He supposed the machine could be coupled up so as to be used as series-shunt, as series, as shunt, or as double shunt; but taking it as he found it, he thought it was not possible to say how it was used. He had studied the parts of Haddan's provisional specification relative to the commutators, and the descriptions in the final specification, as also the claims applicable to the commutators. The claims in the final specification did not go at all beyond a fair carrying out of the invention disclosed in the provisional specification. The Manchester commutator did not strike him as being at all an anticipation of the Brush arrangement, or of any of those claims, because the mode of fixing on the wearing segment was different from Brush's.

Cross-examined: Shunt-winding was not really known till about 1879 or 1880. Wheatstone disclosed it in his communication to the Royal Society, but not clearly. He could scarcely consider that communication, in which a short wire was put across between two poles of the circuit, as being anything like a disclosure of shunt winding. It was virtually a current used in an external circuit while the magnet was excited by a shunt, and so it was a shunt arrangement. It was treated as a shunt arrangement even by Siemens. It struck him that rather more credit was given to Wheatstone than he deserved in that particular matter, which was really of no moment to his fame. Siemens treated shunt as a thing which had been disclosed by Wheatstone. Clark's patent disclosed it with more clearness. Bifurcation of an electric current by splitting or joining two wires in one was a very common thing, and had been so for a very long time in telegraphy. An electrical workman might bifurcate a current, and splitting the wire would readily suggest itself. *Q.* Do you read electricity as meaning electric energy or electric current?—*A.* I do not know. I may say further that it would make no difference to me whether it was called electricity or electric energy, or electric current, in construing this sentence. If electricity meant electric energy, it would be true to say of a series-shunt machine that part of the electric energy was depleted to maintain the magnetism of the magnets, and the remaining portion was used only to produce the electric light. *Q.* Taking it as electric current, if you do not read in the word "only," is not the language consistent with what occurs in a series-shunt machine?—*A.* It is not absolutely contradictory, but the first sentence is very misleading. It was true to say of a series-shunt machine that the portion of the electric current which was not used in the shunt did maintain the electric light. That was true so far as it went, but it also did something else. *Q.* Does not a subsequent sentence give you the additional function which it was to perform if it was series-shunt over and above the producing of the electric light?—*A.* That implies that the current through which the electric light is maintained does pass round the electric magnets. That is consistent with, and, indeed, indicative of, the series portion of a series-shunt machine. There were just two portions dealt with in preceding lines—first, the part which is diverted, and, secondly, the remaining portion which is used to produce the light. These two are exhaustive of the whole. *Q.* Is not the first portion which is diverted consistent only with either shunt or separate excitation? *A.* I think it must be held to mean either the one or the other. I cannot suggest anything else it could mean. *Q.* Does that not leave this difference, that when I add to the first sentence the second sentence I get it that the machine there described must be a machine which has an excitation of the magnets by a series arrangement, and has also excitation of the magnets either by a shunt arrangement or by a separate excitation within the armature?—*A.* Either by a shunt arrangement or by an arrangement in a separate circuit. *Q.* And practically the action of the shunt would be equivalent to the action of the separate excitation?—*A.* Not quite equivalent. They are far from being equivalent. He thought the words used by Varley implied two circuits. He noticed that Brush used precisely the same term, because "circuit" was continually being used for "branch" by writers on that subject; it was an ambiguity. With reference to commutators, Varley said, "when electricity of a very high potential is desired, the commutators may be increased to the same number as the bobbins." That pointed to series among the bobbins in case of high potential being desired. With a machine where the commutators were all connected in series, the idea of separate excitation was not necessarily excluded, because one group might be kept out of the series. If they were all in series separate excitation was kept out. With regard to those passages of Varley where something was said about the results of storing magnetic force and so on, those matters were very much among the *arcana* of the science, and were made more so by the words that were often used. *Q.* If you were describing these operations now, would you necessarily be quite correct according to the scientific knowledge of 1898?—*A.* I hope not. *Q.* In that matter about the storing of magnetism, assuming Varley was wrong in what he says, that would not make any difference upon the working of the machine?—*A.* One of his chief claims is founded upon an idea which, I think, must generally be admitted to be erroneous; that is his first claim. *Q.* You think Varley's actual apparatus for cutting out the armature bobbin at a certain part is not so complete as Brush's was afterwards, because it did not cut it out for long?—*A.* I think

Digitized by Google

probably it would not be so well proportioned as it would have been if that wrong theoretical idea had not influenced him. *Q.* Does not that cutting out of the bobbin at a neutral point, as it is done in Varley, act satisfactorily so far, though it would have acted more satisfactorily if you had cut it out for a little bit longer?—*A.* I think so. *Q.* If you were told as a fact that Varley's machine, No. 29 of productions, had been connected in accordance with the device shown in Varley's sketch, would that convey to your mind a certainty that it had been worked as a series-shunt machine?—*A.* Yes. *Q.* Without being told how it was connected, if you were told that that machine was worked with the lamp produced, and that it was noticed that when the lamp was lighted the magnetism of the machine was greatly increased from what it had been before, would that convey to your mind that this lamp was used in connection with the series-coil of this machine?—*A.* Yes. *Q.* If you were also told that when the lamp was out the magnets of the machine were noticed to be excited, as evidenced by keys and so on sticking to them, and by sparking at the brushes, would that indicate to your mind that the magnets of this machine, besides being excited by the series arrangement, were also excited either by the shunt or a separate excitation arrangement?—*A.* No; because residual magnetism may be amply sufficient to produce these effects.

WM. HENRY PREECE, electrician to the General Post Office, deposed that his attention was first called to a shunt-wound machine by a Paper read by Sir Wm. Siemens before the Royal Society in 1880. He was aware that Sir Charles Wheatstone had read a Paper developing the idea of shunt before that, but he simply alluded to the experimental use of shunt, and did not in any way indicate the construction of a shunt machine. He had since heard of Clark's patent, but he had not heard of it before 1880. So far as he knew, no machine had been made in conformity with that patent before 1880. He had examined Varley's machine, No. 29 of productions. It was a very complicated machine, which would have an excessive waste of electric energy. If that machine were used to excite an electric light with the lamp now produced, it would require about 4-horse power, and of that 3½ would be wasted in the machine, and only one-half horse power would be employed in generating the light. He thought it would have been extremly difficult, if not absolutely impossible, for a workman in 1876 to have made a series-shunt machine from the directions contained in Varley's specification. The whole thing was really an improvement upon a machine that existed and was patented before by Varley. The drawings were scarcely consistent with the letter press. The part of the specification dealing with the question of winding with two wires was certainly inconsistent with the rest of the specification. There were two-pole machines, four-pole machines, and six-pole machines, and they were all referred to as though they were ordinary series-wound machines. When they came to the specification dealing with the question of two wires, they found something that was not consistent with anything else that appeared in the specification, but it was to some extent consistent with something that appeared in Varley's previous specification. It was very well known about that period that Holmes and Wilde excited their machines by a separate circuit taken from a part of the armature. The wrapping of magnets with two wires was not a novelty in 1876; it was a most common form of apparatus, especially in telegraphy. *Q.* Taking an ordinary series-shunt machine, as described in Brush's specification, the description about the wrapping of the magnets would not lead necessarily to the construction of a series shunt-machine?—*A.* It would depend upon how the wires were connected, and where they got the electricity from. These matters were left entirely indefinite in Varley's specification. The machine described in Haddan's specification was undoubtedly a useful machine, and was a decided improvement upon either the series or the shunt. He thought that from the specification a workman would have no difficulty in constructing a machine of the nature there described. He thought that sheet four of the drawings, taken with the directions in the specification, would lead to the making of a machine which would tend to constant potential. Brush's specification completely disclosed the invention of series-shunt winding. It would be quite impossible in such a specification to give directions which would enable a workman to make every type and variety of machine to produce electricity at constant potential. Even at the present day, and in view of all the knowledge acquired since 1878, it was usual to have trials, to see whether the machine was properly compensated. The machine described in Haddan's specification was a compensating machine. He had on 4th February, 1887, made some experiments with the early Brush compound-wound machine for electro-plating. The current varied during the experiments from 300 amperes, which was a very large current, to nothing, and the potential remained very fairly constant. There was a variation between the extreme load and no load of 22 per cent.

Cross-examined: So far as constant potential was now understood, and as desired for the incandescent light, they would not dream of accepting a machine with 22 per cent. variation. At Messrs. Crompton's works they could nowadays make pure shunt machines which they would guarantee to within 10 per cent. of constant potential. The usual specification limit was 5 per cent. in series-shunt machines. Compensation in electro-plating would be got by a pure shunt machine, but not to the same extent as in a series-shunt machine. In making the calculation as to the economy of Varley's machine he had assumed that it was connected up as a series-shunt machine. *Q.* Taking Varley's machine at its own date, and not in view of the machines that had been since discovered, was it such a bad machine when Varley invented it?—*A.* I should say that if it was chucked on the dust heap it must have been rather a poor thing. *Q.* Do you think it was a poor machine in 1876?—*A.* I think if it had not been a poor machine we should have heard something about it. He did not express an opinion about the efficiency or non-efficiency of Wilde's machine. He had never devoted his attention to finding out what was the percentage of waste in the earlier machines, such as Wilde's, Ladd's, and Ruhmkorff's. He could not say whether Varley's machine wasted more or less than they did. *Q.* Is there any reason why a machine which has three bobbins to each group should not be a series shunt-wound machine?—*A.* It would not be at all consistent with what follows. *Q.* But what is inconsistent in that with the idea of the machine being wound series-shunt as regards the field-magnets?—*A.* That can only possibly refer to one circuit, whether series or shunt; it does not say a word about an armature circuit. He was obliged to take this matter in connection with the previous machine of Varley, and in his patent of 1867 he distinctly defined how the field-magnets and bobbins were to be wound. The 1876 specification simply described the commutators of the machine, and made no reference to the field-magnets.

Re-examined: Figure 17, sheet 3, of Varley's drawings showed the arrangement of the commutators described in the specification. The winding was series winding. No other sort of winding was shown.

ROBERT PERCY SELLON, chief electrician of the Anglo-American Brush Electric Light Corporation, said the patent now in question was purchased by the defenders in December, 1880, from a previous company, who had purchased it from Brush in 1879. The price paid to Brush for the English and Colonial patents was £27,000, and the price paid by the present company for the English patent was £25,000. The patent had been twice amended by disclaimer, in 1882 and 1885. The series-shunt-wound system, according to the Brush patent, was introduced immediately upon the formation of the original company in the end of 1879. For electro-plating the Brush Company commenced to supply series-shunt machines in 1880, and they had supplied them continuously since. All the machines sent over from Brush between 1880 and 1883, and used for electro-plating and electro-typing, had been subjected to test, and it was found that they maintained the potential constant to within 15 or 20 per cent. He had examined the proportions of the windings of some of the machines, and they were very similar to the proportions shown on Brush's drawings. Up to the summer of 1882 witness knew of no series-shunt dynamo in the market for any purpose whatever, with the exception of those supplied by the Brush Company under their patent. The first dynamos that were made specially for incandescent lamps were constructed by Brush in July, 1882. In the summer of 1883 the Brush Com-

pany in England commenced to supply series-shunt machines specially for incandescent lighting. It was in 1884 or 1885 that the Brush Company first discovered that their patent was being seriously infringed, and they insisted on licenses being taken. Messrs. Siemens and twenty-two of the leading manufacturers in the country had taken licenses. The only persons who contested their rights were Messrs. Crompton and several minor firms. An action was brought against Messrs. Crompton for infringing the patent right, and in 1887 they consented to judgment, paid £2,000 costs and damages, and accepted licenses, the Brush Company giving them a rebate of practically one-fourth in consideration of their assigning to the company a subsequent patent on the same subject of series-shunt. The only other litigation upon the patent was an action by the Brush Company against the Orient Company, in which judgment was given for the pursuers. As regarded their commutators, their claims were merely carrying out in detail, and in various combinations, the inventions foreshadowed in the provisional specification. Claim 6 said nothing about the insulating segment "T" being metallic. It was a claim for the combination of details all tending to simplify the mechanical construction of the commutator, diminishing the number of gaps, and making it more cylindrical, durable, and simple.

Cross-examined: [Shown statement of the stock of the Brush Company at May, 1883.] That list showed no series-shunt-wound machines in stock. He did not know how much of the £27,000 paid by the original company was paid to Brush himself. *Q.* You do not know whether he only got about £6,000?—*A.* I do not suppose he got the whole, because there was a second party who was taking part in the sale.

This closed the proof for defenders, with the exception of the evidence of Mr. Brush, which is to be taken in America by commission. Counsel will afterwards be heard, and the judgment of the Court will probably be given before the end of January.

United Telephone Company v. Ericsson-Bell Telephone Company.

On Tuesday last Lord Trayner closed the record in an action at the instance of the United Telephone Company, London, against the Ericsson-Bell Telephone Company and Charles Bell, the only known partner of that firm, which carries on business at 29, Waterloo-street, Glasgow. The pursuers ask that defender should be interdicted from infringing letters patent assigned them by the Edison Telephone Company in 1880, and by Alexander Graham Bell, Boston, in 1878. There are also conclusions for £1,000 damages, and that defenders should deliver up all the instruments which have been constructed in infringement of pursuers' letters-patent. The defender had a stall in the recent International Exhibition in Glasgow, and the pursuers aver that he sold instruments there which were an infringement of their patents. The defence is a denial of the infringement, and defender pleads that the damages claimed are excessive.

United Telephone Company (Limited) v. Edward Paterson.

This action came on for hearing before Mr. Justice Chitty, on the 4th inst. The plaintiffs asked for an injunction against the defendant, who carries on business at the European Works, Pownall-road, Dalston, for infringement both of the Edison and of the Bell patents.

Mr. MACRORY, who appeared for the defendant, admitted the infringement and submitted to an injunction in the usual form, and to an order directing the defendant to deliver up all infringing instruments in his possession or under his control, and directing an inquiry in chambers as to the damages sustained by the plaintiffs, the defendant to pay the costs of action.

The plaintiffs claimed their full costs, charges and expenses, as between solicitor and client, under the 31st section of the Patent Act, on the ground that they held certificates that the validity of the patents had been questioned in previous actions, but Mr. Macrory, on behalf of the defendant, argued that the plaintiffs ought not to have their full costs in this case, and asked the judge, under the 31st section, to certify to this effect.

Mr. JUSTICE CHITTY remarked that the defendant had on his own admission infringed the patents, and that he saw no reason for depriving the plaintiffs of the full costs which the statute gave them.

COMPANIES' MEETINGS & REPORTS.

The Swan United Electric Light Company (Limited).

The following is the sixth annual report of the Directors, to be presented at the ordinary general meeting of the Company, to be held at the Cannon-street Hotel, London, E.C., on Tuesday, December 18, at 12 noon:—

1. The accounts which are presented to the shareholders are for the year ending 30th September, 1888.

2. The business has increased on the Continent generally, and has resulted, after paying all current charges and making fair allowance for depreciation of plant and machinery, in leaving a credit balance of £8,332. 1s., which the Directors will recommend shall be carried forward.

3. The agreement with the Compagnie Continentale Edison, which was unanimously approved by the shareholders at the extraordinary general meeting, held on 5th June last, was also approved by the shareholders of the Compagnie Continentale Edison, and has resulted in the formation of the Compagnie Générale des Lampes Incandescentes, which has its seat in Paris, and who are erecting a factory with all necessary appliances for a large output of lamps to meet the established and growing demand.

4. The litigation as to the Swan and the Edison patents is still dragging on in Germany. The negotiations between the Company and the representatives of the Edison patents in Germany have been dropped for some time, but the Directors will avail themselves of any fair opportunity which may be afforded of re-opening the negotiations with a view to a satisfactory settlement in Germany.

5. The Directors who retire by rotation are Mr. J. W. Swan and Mr. C. H. Stearn.

6. Messrs. Quilter, Welton and Co., the auditors, also retire.

Woodhouse and Rawson (Limited).

An extraordinary general meeting of this company will be held at the Cannon-street Hotel, Cannon-street, E.C., this day (Friday, December 14), at 3 o'clock, for the purpose of considering, and, if thought fit, passing, a resolution for the sale of the property of this company to a larger company now in course of formation. A temporary auditor will be appointed.

CITY NOTES, &c.

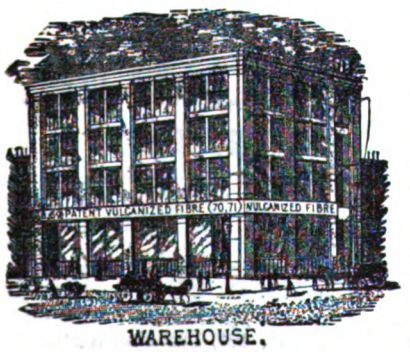
BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended December 7th, 1888, amounted to £5,917.

RIVER PLATE TELEPHONE AND ELECTRIC LIGHT COMPANY (LIMITED) (IN LIQUIDATION).—Holders of share warrants to bearer in this company are requested to send in their warrants forthwith to the liquidators at the offices of the company, New Broad-street, E.C., in order that the payment due thereon may be made before the liquidation is closed. Otherwise application to the Court of Chancery for payment will be necessary.

THE MINING AND GENERAL ELECTRIC LAMP COMPANY (LIMITED).—Lord Crawford writes to the *Financial News* as follows:—"Sir: I observed in Wednesday's papers a notice that the shares of this company were allotted. I think it only right, as my name and the names of my friends, the Hon. Reginald Brougham and Mr. James G. Stephen, were on the prospectus, that the public should know we had resigned our seats at the board prior to the allotment.—I am, sir, yours, &c., CRAWFORD, 2, Cavendish-square, W."

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended December 7th, 1888 (after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, Limited), were £4,905.

THE NON-CONDUCTOR OF ELECTRICITY.



WAREHOUSE.

VULCANISED FIBRE,

PATENTED.

This new material is supplied in two qualities, Flexible and Hard.

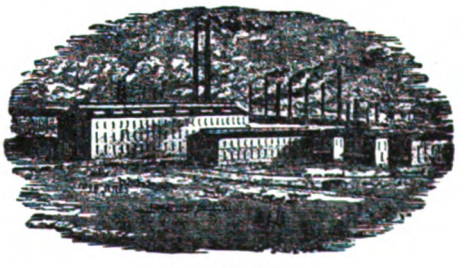
The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.



FACTORY.

MOSSES & MITCHELL, 70 Chiswell-st., London, E.C.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 553.—Vol. XXII. FRIDAY, DECEMBER 21, 1888. Price 4d.

NOTES.

The Vestry of Paddington can hardly fail to have been considerably surprised on learning from Mr. Mackie that a profit ranging from 37 to 50 per cent. upon the capital invested may be looked for in connection with the proposed electric lighting scheme in that district, and the ratepayers will probably much lament the fact that so considerable a source of revenue has been so long untouched. It is true that Mr. Mackie is perfectly honest in setting forth the very special conditions under which this delightful result may be looked for, but in a report prepared for the public consumption it would, we think, have been better to have made it quite clear that the condition in question is wholly chimerical and unattainable. No electrical engineer requires to be told that to estimate for central station lighting on the basis of a total annual output of 2,186 hours under full load is preposterous; but the Paddington Vestry may not be aware of the fact, and therefore we think that Mr. Mackie ought to have told them so. A more reasonable basis of calculation would be about two-fifths of Mr. Mackie's figure, or, say, 875 hours per annum. If the estimated revenue from incandescent lighting be reduced in this proportion, and the same reduction be made in the working expenses so far as they are affected thereby, then accepting the remainder of Mr. Mackie's figures, it appears that with a tariff of 7¼d. per B. T. unit the investment will not even pay the 5 per cent. interest on the borrowed capital. There are other details upon which the estimates are open to criticism, but we will only stay to inquire whether £100 (less than 1 per cent.) is a reasonable allowance for "contingencies" on an expenditure (in Scheme A) amounting to over £10,000?

Mr. Mackie has evidently gone to very considerable trouble in the preparation of these estimates, and we therefore the more regret that he should have based the revenue estimate upon such totally erroneous assumptions. And we feel bound to express our objection to the presentation of documents of this description, which can only do harm to the progress of electric lighting. Fortunately in this case we have reason to suppose that very little injury can result, since the Vestry will no doubt await the report of Prof. Forbes before taking further action.

From a letter in another column it will be seen that Dr. Oliver Lodge declares himself a disbeliever in the so-called abnormal magnetisation which is frequently alleged to occur with Leyden jar discharges. In a long series of experiments Dr. Lodge invariably found the magnetisation of a normal character. This is admittedly strange, in face of the fact that so many observers have come to the contrary conclusion. We may suppose, however, that the experiments in question were primarily directed to ascertaining the magnetic permeability of steel under oscillations of varying frequencies (*see* Dr. Lodge's Papers on "Lightning Conductors," in our last two issues). If so, it is just possible that the permanent conditions of the experiment happened to be such as to produce uniformity, and that with more varied conditions a less uniform result would have been attained. It will not be forgotten that a possible explanation of the latter effect was recently given by Prof. Ewing.

The introduction of the Waterhouse constant-current dynamo has drawn attention to the method of obtaining regulation by the aid of a third brush, whose position on the commutator is adjusted automatically or otherwise. In a Paper "On the Regulation of Dynamos by Means of a Third Brush," Mr. E. Caldwell recounts a series of experiments which he has carried out at the Cornell University in order to elucidate the theory of this effect. In this somewhat remarkable Paper it is shown that a simple explanation can be given of all the changes which occur when either the position of the brush or the resistance in circuit with it are subject to variation, and what are the conditions necessary for constant-current regulation. He remarks that the arrangement is really equivalent to a machine in which one set of field coils is made to do duty for both shunt and series winding, and, moreover, the shunt coil or its equivalent acts either as a cumulative or differential coil, according to circumstances. In the experiments described it appears that it was found necessary to alter the position of the brush or of the resistance connected thereto, and so far we have no radical improvement upon other well-known methods of constant-current regulation in which brush movement or field circuit regulation is necessary.

In the second part of the Paper the author points out that the "third-brush" method may also be used as a means of maintaining constant potential, and he claims for this arrangement the further advantage that the brush may be fixed in position, and that the resistance in circuit with it may be also fixed. The importance of this suggestion is so evident that its validity merits careful examination. We do not for a moment dispute that the effect described by Mr. Caldwell was

Digitized by Google

obtained, and is obtainable. But, unfortunately, the experiments seem to have been carried out upon an old-fashioned machine of small size, and the author has apparently overlooked the fact that the result described must have been in reality due to prejudicial inductions in the armature, such as were first elucidated by Mr. MORDEY in his well-known investigation of the early Schuckert machines. In fact, as Mr. MORDEY has himself suggested to us, very little consideration is sufficient to show that a current through the third brush, varying on either side of zero according to the total current generated, can only be accounted for by the existence of a variable equipotential point on the commutator. That is to say, the distortion produced by the armature current is so great as to entirely upset the conditions of potential distribution upon the commutator which should prevail in any well-designed dynamo. The mere fact that a third brush can be placed on the commutator at a point between the main brushes may be taken as sufficient evidence that the distribution of potential is abnormal and bad; for if no excessive sparking occurs at the third brush, it can only be because this brush is at a false neutral point. Had Mr. CALDWELL conducted his experiments on any good type of modern dynamo built for incandescent lighting, he would certainly have been unable to obtain the regulating effects that he describes; and we very much doubt whether the disadvantages accompanying the design are counterbalanced by the possession of such a method of regulation. In the case of constant-current machines designed for arc lighting, we do not say that the method is necessarily bad in practice.

A FEW days ago we witnessed a repetition of an experiment which was lately shown by the London Electric Supply Company to the representatives of the Board of Trade, and which may, perhaps, tend to reassure those who regard high-tension currents with an unnecessary degree of dread. One lead of a 2,500-volt alternating-current circuit was carefully placed to earth in damp soil, and it was shown that no danger was incurred, and, indeed, very little sensation was experienced, by touching the other lead, even when the experimenter himself stood on damp soil. The second lead was old and weather-worn, and had been in use for some three years, so that the experiment may be said to have taken place under very rigorous conditions. The presence of the 2,500 volts was made visible by stringing twenty-five 100-volt incandescents across the wires. The existence of a circuit to earth was also shown by the sparking which took place on grounding the lead. It is to be hoped that the Board of Trade will see reason in this for insisting upon good workmanship and materials, rather than for imposing any arbitrary limit of potential difference.

IT is decidedly unpleasant, not to say alarming, to have your telephone burnt out by a "cross" with an electric lighting wire; but seeing how easily and cheaply all danger of such a disaster may be averted, there is no real occasion for the state of terror and alarm under the influence of which the writer of a letter in the *Standard* was evidently labouring. The insertion of a safety fuse (costing a few pence only) will provide a perfect remedy, even in the event of a cross—which, of course, ought never to occur—by some mishap occurring. We may note further that since all electric light wires are covered with insulation, it does not necessarily follow that any damage will result even if the wires do come in contact. The United Telephone Company will, however, do well to put in safety plugs for all their subscribers whose wires traverse the electric lighting area, and there will be an end of the matter. Considering that over a hundred miles of overhead high-tension circuit exists in London, the fact that this is the first accident of the kind speaks volumes for the care and skill with which both telephone and electric lighting wires are now erected.

As to the actual facts of the case in point, we learn that the mishap occurred in Berners-street, where a wire from Messrs. PRITCHETT'S lighting station crossed the telephone wire at right angles, the latter being underneath. Contact by some means having been established, the telephone wire was burnt in two, and the telephone coils were frizzled up. The end of the wire seems to have fallen across a line belonging to the Exchange Telegraph Company, and the "sparks which flew across the room," and the "shock" felt by the lineman, were caused by the Exchange Company's current, and had nothing to do with the electric light wire. Of course the lineman was not hurt, and gives a very different version from that of the *Standard* correspondent. In the Telephone Exchange an indicator was frizzled.

MUCH anxiety is evinced in Parliament by certain noisy members lest the Government should pay more than the price of old iron for the cables of the moribund Submarine Telegraph Company. It is an ugly sign of the times when public men, otherwise honest and sensible, allow themselves to employ language worthy only of the Commune. The ostensible pretext is to prevent the tariff being kept too high because of a fancy price having been paid for the lines. But that is not at all likely to happen. A fair price, however, ought certainly to be paid for a system of cables which still represents a "going concern," although not an exclusive one. Members of Parliament should remember that, if the monopoly expired, the Company did not, and to extinguish it compulsorily in the interests of the public a liberal bonus on the working plant ought not to be begrudged.

WITH the discouragement of Barnet to contend against, it is well to remind the public that for one station which is a failure there are at the present time in operation in this country no less than twenty-three central electric lighting stations, almost all of which are perfectly successful in every sense of the word. As one of the most striking examples, we may mention the Thomson-Houston plant which has been run for the last two years by Messrs. TASKER, SONS AND Co. at Sheffield, and which has from the very first worked without a single hitch. At the present time over 100 2,000 candle-power arc lamps are supplied from three 50-light machines, and a 600-light Mordey alternate-current transformer plant for incandescent lighting will be ready for use at the beginning of the year. As an

Digitized by Google

illustration of the steadiness of the arc lighting, we may mention that two billiard tables have been so lit from the commencement, and perfect satisfaction is expressed.

REPRINTING a recent leader of ours, entitled "Electricity our Defence," the *Electrical Review* of New York reproachfully reminds us that the title we borrowed, with a compliment to the "American press" for its felicity, was the *Review's* very own, adding these significant words, "The name of this journal is not the 'American Press.' Does our neighbor see the point?" If our neighbour will pardon us for saying so, we rather think there is more handle than point to this complaint. We certainly paid a high compliment to the newspaper in question—much higher than if we had mentioned it by name. On reflection, probably, our contemporary will see the point of *that* remark.

The Berne-Geneva Telephone Line.—Direct telephonic communication between Berne and Geneva has just been opened.

Vienna.—A company has recently been floated in Vienna with a capital of a million florins for the purpose of constructing a central lighting station in the Mariahilf quarter.

Church Lighting in London.—We understand that the Metropolitan Electric Supply Company has offered to light St. Martin's Church, at Charing-cross, by electricity. The Oratory at Brompton has been so lighted for some time.

Chelsea.—At a meeting of the Chelsea Vestry last week, the Surveyor, Mr. Strachan, reported that the Chelsea Electric Supply Company proposed building their central station in Draycott-place, with a basement below the level of the street sewer.

Electric Lamps for Locomotives.—Good results having been obtained with the electric lights used on the locomotives of the Berlin-Stralauer-Rummelsburg line, it has been decided to extend their use to the locomotives on the railway running round Berlin.

The Eastern Cable Companies.—We have received a very neat and extremely useful paper cutter, on which, besides an almanac for 1889, the cable systems of the world are clearly depicted, issued by the Eastern and Eastern Extension Telegraph Companies.

Southwark.—At a meeting of St. Olave's District Board of Works last week it was resolved not to comply with a request from the House-to-House Electric Supply Company (Limited) to assist them in obtaining a license to supply the district with the electric light.

Pordenone.—On the 23rd September the central station at Pordenone (Italy) started work. The station is 2½ kilometres outside the town, and power is furnished by a 30 horse-power Girard turbine. At present only 280 incandescent lamps, run off three Zipernowsky-Déri transformers, are in operation.

Suakin.—A *Standard* telegram from Suakim says:—"Engineer White, of Her Majesty's ship 'Racer,' and Engineer Mason, have just completed an installation of the electric light at various points of Quarantine Island, including the hospitals there. A trial has been made, and the system has been found to work satisfactorily."

The Transvaal Telegraphs.—We learn that the Transvaal telegraph system is at present almost in a state of collapse, the mail service generally beating the wire. Mr. Sivewright, the well-known telegraph engineer of Cape Town, is now on his way to the country to see what can be done in the interests of the Eastern Telegraph Company's customers.

The Telephone on the West Coast of Africa.—The St. Paul-de-Loanda Telephone Exchange has nearly 100 subscribers, chiefly merchants and Government officials. The telegraph line between Loanda and Dondo, a distance of 125 miles, is almost exclusively used by the English, and affords great facilities to the planters in the interior.

Rotherhithe.—At a meeting of the Rotherhithe Vestry last week a letter was read from Messrs. Deacon, Gibson and Medcalf, on behalf of the Electric Supply Corporation (Limited), stating their intention to apply for a provisional order for the supply of electricity in the parish, and asking for the Vestry's support to obtain the same. It was resolved to refer the matter to committee.

Strand District Board of Works.—At the meeting of the Strand District Board of Works last week, intended applications to supply electric lighting in that district were received from the Metropolitan Electric Supply Company, London Electric Supply Corporation, House-to-House Electric Light Supply Company, Electrical Power Storage Company, and the Westminster Electric Supply Corporation, and referred to the Lighting Committee.

The Battle at Suakin.—The first telegram announcing the victory at Suakin, yesterday morning, was received in London, over the Eastern Telegraph Company's lines, only twenty minutes after the conclusion of the battle, while the second telegram, giving details, received shortly after 7 a.m., occupied thirty minutes in transit. The first message was handed in at 8.30 a.m. Suakin time, which is about two hours and a-quarter in advance of English time.

The Royal Institution.—The list of probable arrangements for the Friday evening meetings at the Royal Institution contains several events of more than usual interest to electricians. On Friday, February 8th, Sir William Thomson has a Paper on "Electrostatic Measurement," and a week later Prof. Rücker will read a Paper on "Electrical Stress." Finally, on March 8th, Dr. Oliver Lodge will have something further to say on "The Discharge of a Leyden Jar."

Okehampton.—The public supply of electricity upon a very limited scale is about to be undertaken at Okehampton by Mr. Henry Geen. Water-power is available to the extent of about 125 incandescents—the candle-power of the lamps has not been given us—and since gas costs 5s. 10d. per thousand in Okehampton the economic conditions are evidently favourable. Several houses in the town are now being wired, and arrangements are being made to lay the wires underground.

Contract for an Electric Launch.—Mr. James Adam, boat-builder, Cove Yard, Gournock, has received an order for an electric launch, to be built from the designs of Mr. G. L. Watson. Her dimensions are as follows:—Length, 50ft.; breadth, 7ft.; and depth, 3ft. 6in. She is to be built of the finest oak, and to have elm and cedar plankings. The modelling of the launch shows a cutwater bow and elliptic stern, with a house amidships. She is to be propelled by electric power, and is to be built without beams.

The City and Guilds of London Technical Institute.—On Wednesday evening the prizes and certificates gained by the successful students attending the schools, in connection with the City and Guilds of London Institute for the Advancement of Technical Education, were distributed at Fishmongers' Hall by Sir Lyon Playfair, M.P. In the course of his speech Sir Lyon Playfair said "he considered that the country owed a great debt of gratitude to the City and Guilds Institute, which had set a noble example to the whole kingdom."

St. George's (Hanover-square).—A meeting of the St. George's (Hanover-square) Committee of Works was held last week. Some discussion was raised upon an application for permission to lay a gas main in one of the parish footways, but Mr. William Adkins strongly objected to permission being given, as he thought that footways generally should be entirely reserved for the cables and electric lighting companies. Permission was given for the main to be laid in the roadway only.

Breakdown of the Fredericia-Calais Cable.—The submarine cable running from Calais to Fredericia (Denmark) has been interrupted since the beginning of the month, and telegrams to the North are being sent *vid* Berlin; the interruption has occurred near the middle of the cable. This cable, which belongs to the Great Northern Telegraph Company, was laid in

Digitized by Google

1873, and is some 380 miles long; it connects France with Denmark, Scandinavia, and Russia, and thence with China.

Extension of Telegraphic Service.—The Postal Telegraphic Authorities are making arrangements for an important extension of the telegraphic communication between Glasgow and the north-west of England. From Glasgow the new line of wires will be carried along the Carlisle-road until Beattock, in Dumfriesshire, is reached. The route will then be through Central Annandale to Lochmaben, thence by Dalton to Annan, and across the Solway Firth to England. Several places at present without telegraphic communication will be accommodated.

Central Station Lighting at Derby.—We learn that Messrs. John Davis and Son, of Derby, who some time ago added electric lighting to their regular business of mining engineers, are now engaged in laying down a small central station lighting plant at their works, from which a part of the adjacent district will be lit. The plant first installed will have a capacity of 500 lamps, and will include a storage battery. This firm has also in hand some important orders for electric pumping and hauling plants for mining work, including an order for a gold mine in the Transvaal.

The Electric Light in the Royal Navy.—The Admiralty have decided to provide complete electric lighting installations on board the following war-ships:—The "Nile," "Hero," "Agamemnon," "Colossus," "Conqueror," "Shannon," "Forth," "Champion," "Basilisk," "Beagle," "Redbreast," "Redpole," "Magpie," "Goldfinch," "Lapwing," "Ringdove," "Widgeon," "Thrush," "Kingfisher," and "Sparrow." A contract for the supply of the plant has been entered into with Messrs. Willans and Robinson, at a total cost of £11,095. Three sets are to be supplied to the "Nile," two each to the "Agamemnon" and "Forth," and a single set to each of the other vessels.

"Our Christmas Annual."—We gladly notice this Christmas annual (Woolwich: F. J. Cattermole; London: Simpkin, Marshall and Co.), partly because of the charitable object with which it is published, but chiefly, perhaps, because many of the contributions are from the pens of well-known telegraph men. The proceeds of the sale are distributed amongst deserving cases of poverty and distress. The lady who undertakes the double task of editing the Annual and superintending the charity asks that the literary shortcomings may be pardoned; but, in reality, the stories are quite up to the average of this class of literature, and in some instances superior.

Ipswich.—At a special meeting of the Ipswich Town Council, held last week, it was decided to grant permission to Messrs. Lawrence, Paris and Scott to erect overhead wires for electric lighting purposes, such permission to extend over a period of twelve months only, in order to give the company time to make application to the Board of Trade for a provisional order, and to enable them meanwhile to proceed with the undertaking. Owing to the necessary period of one month not having expired since notice was received of the intention of the company to apply for a license or provisional order, the assent of the Council to the application could not then be given. A special meeting for this purpose will be held on January 9th.

Electric Lighting in the Inner Temple.—A petition to the treasurer and benchers of the Inner Temple is being extensively signed by the members of that Inn against the works at present in progress, in the Inner Temple Gardens, in connection with the installation of the electric light in the Inner Temple. The petitioners point out, among other things, that the erection of the engines, dynamos, and works in the Inner Temple Gardens will not only seriously depreciate the value of the chambers in the vicinity, but will constitute a permanent eyesore and disfigurement to the gardens. The petitioners, therefore, pray that if the extension of the electric light in the Inner Temple cannot be carried out except at such a sacrifice, the scheme be forthwith abandoned.

Leamington.—The Leamington correspondent of the *Birmingham Daily Gazette* says:—"Very little doubt is now entertained that Messrs. Chamberlain and Hookham's experiments with the lighting of the streets of Leamington by electricity will come to an end next year. The present contract price for the supply of electricity to the specified area is £400 a year. The amount previously paid to the gas company for lighting the two thoroughfares was less than £200 a year. In view of the disproportionate increase in the cost of electricity as compared with gas it is believed that at their meeting on the 14th prox. the Leamington Corporation will give the required twelve months' notice to determine the supply of the current to the public lamps.

Metropolitan Board of Works.—At the Metropolitan Board of Works, on Friday last, a letter was received from Messrs. Latimer Clark, Muirhead and Co., on behalf of the St. James and Pall-mall Electric Light Company (Limited), giving notice of their proposal to lay electric light mains in Duke-street, St. James's, and certain other places in that neighbourhood. A letter was received also from Lord Crawford, on behalf of the London Electric Supply Corporation (Limited), asking permission to lay a main for conveying electricity through part of the Victoria Embankment Garden, and stating that Her Majesty's Office of Works had already granted the company permission to lay mains through the War Office Garden and along the St. James's and Green Parks. The subject was referred to the Works and General Purposes Committee.

St. Martin-in-the-Fields Vestry.—At their last meeting the Vestry proceeded to consider a motion to give consent, under rule 8 of the rules made by the Board of Trade with respect to applications for licenses and provisional orders under the Electric Lighting Acts of 1882 and 1888, to the granting of a license by the Board of Trade authorising the Metropolitan Electric Supply Company (Limited), to construct and maintain electric lines and works, and to supply electricity within the parish. The clerk (Mr. G. W. Murnane) said the Vestry gave their assent to a Bill last June, and he asked for leave to arrange with the solicitors to the Bill. They had introduced several interlineations into the arrangements proposed; some of them were of a technical nature, but he could not advise the Vestry to adopt them. He had seen the solicitors on the question, and they had agreed to his terms. He had conferred with Mr. Harry Wilkins, the Vestry Clerk of St. James's, Westminster, and they worked in concert. He considered the Vestry might give consent. This was done.

The Lighting of the City.—At the last meeting of the Commission of Sewers Mr. Treloar asked when they were to receive the report of the Streets Committee as to electric lighting, and why it had been delayed. Mr. Bridgman replied that the committee had done all they possibly could in the matter. They had decided upon the principle upon which the conditions for tendering would be based, and the matter was now with the officers. The engineer had communicated to him, through Mr. Preece, the electrician consulted, his views, which had been sent to the solicitor, who had considered the documents and returned them. The engineer was putting the matter into proper shape, and as soon as this was done the committee would be glad to discuss it. The committee had determined that the matter should be settled before they went out of office. Mr. Rose-Innes asked whether it would be open to private persons or companies to tender. Mr. Bridgman replied that it would be publicly advertised, and the conditions would be sent to those who applied to tender.

Westminster.—At a meeting of the St. Margaret's and St. John's (Westminster) Vestry last week the Parliamentary Committee reported that, in accordance with the instructions of the Vestry, "to fully inquire into the whole question of electric lighting," they, as a commencement of the inquiry, had requested information on the subject from several metropolitan local authorities. They had had under consideration notices of intended applications for provisional orders to produce and supply electricity within these parishes by the Metropolitan Electric Supply Company (Limited), the Westminster Electric Lighting Company, and the London Electric Supply Coporation, and recommended that they should be opposed. The committee also reported that they had empowered the solicitor to the Vestry (Mr. Warrington Rogers) to instruct the Parliamentary agents to draw and lodge formal objections against the licenses now before the Board of Trade, "on the ground that the Vestry should retain the control of the lighting of the parish

Digitized by Google

in its own hands." The report and recommendation were unanimously agreed to.

Opposition to the Pall Mall Electric Light Company's Scheme.—Mr. E. C. Keevil, who, at the last ordinary meeting of the St. James's Vestry, complained of the huge smoke shaft to be erected within 200 yards of Marlborough House, the Carlton Club, and St. James's-square, at the central station of the Pall Mall Electric Light Company in Mason's-yard, has issued a circular to the ratepayers and inhabitants of the Pall Mall Ward, in the hope of convening a public meeting for the purpose of obtaining an injunction to remedy the contemplated serious nuisance. He points out that the vibration of the machinery, which will be of a very massive character, together with the smoke of the works, going on day and night, will be so great a nuisance that many houses in the immediate neighbourhood will become vacant, as was the case in Paddington. Such an installation in their very midst was calculated to seriously injure the interests of clubs, hotels, and private residents. We may, however, add that Mr. Keevil must not take the Paddington installation as any criterion of what an electric light station need or ought to be.

Electric Lighting in the Houses of Parliament.—On Monday last Mr. Howorth asked the First Commissioner of Works whether, during the ensuing recess, he could see his way to make such an extension of the electric lighting arrangements in the House as would check further injury to the stonework in the corridors and staircase leading from the Star Court to the Commons lobby, and whether it would be possible to carry the electric light into the different rooms connected with the Reporters' Gallery.—Mr. Plunket: I quite agree in the desirability of the objects sought by my hon. friend, and I have under consideration a scheme for extending the electric lighting of this building, which would include and go somewhat further than the suggestion of my hon. friend; but the cost of the installation would be considerable, and I must obtain the opinion of the Treasury upon its financial aspect. I fear it would not in any case be possible to complete the arrangements earlier than Easter.—Sir J. Swinburne inquired whether the right hon. gentleman was aware that the electric light had been so dim in the library that members had had to use candles as auxiliaries.—Mr. Plunket thought it must be very seldom that candles were used. He had never seen them in the library.

The Electric Light in Land Warfare.—On Saturday night some interesting experiments were made on Hampstead Heath for the purpose of testing the capacity of small electric hand-lamps in searching for the wounded men left after a battle, and thus more rapidly than hitherto bringing the sufferers within the reach of surgical aid. The experiments were made by the officers and men of the London Division of the Volunteer Medical Staff Corps, an organisation which already consists of four efficient companies, largely composed of medical students, and for which a fifth company is now in process of formation. The corps, under Surgeon-Commandant Norton, accompanied by ambulance waggons, and provided with stretchers, halted upon one of the Heath roads at a time when the thick mist still hung heavily upon the lower grounds; and having established a field hospital in a rather dreary-looking spot, poorly sheltered by bare trees, sent out its searching stretcher parties to pick up the bandsmen who had been distributed over the open ground at some distance off, to simulate the wounded left from a fight during the daylight. By the aid of the lamps thus brought into such use for the first time, the men sought were found with comparative rapidity, the lights being sufficient also to enable the trained ambulance men to apply preliminary bandaging upon the spot, and before loading the stretchers, which by other lights at the waggons were guided back to the road. There the men were carefully placed in the vehicles and conveyed to the field hospital, where the examining surgeons found very little to correct in the treatment adopted under such disadvantageous circumstances. The results achieved indicate sufficiently well, says the *Daily News*, that the electric light thus used would be of immense value, and tend greatly to reduce the suffering of men left upon the field at the close of a fight.

Kensington Vestry.—At the last meeting of this Vestry the Special Committee for Electric Lighting reported that they had considered the letter from the Chelsea Electricity Supply Company (Limited), asking for a way-leave for an electric main in Ovington-gardens, Brompton-road, for the purpose of connecting certain mains of the company, and reporting that the committee are not prepared to advise the Vestry to accede to such application, and the Board of Trade have stated that they do not propose to entertain any further applications from electric lighting companies for licenses in respect of such areas in the metropolis. A deputation consisting of Mr. Alexander S. Hill, Q.C., M.P., Sir Theodore C. Hope, and Mr. Charles Fish attended the committee on behalf of inhabitants in the vicinity of Queen's-gate, urging that permission should be granted to the Kensington Court Company for the extension of their mains in this direction, and referring to the inconvenience by the delay in granting licenses for the supply. The committee recommended that in the event of application being made by the Kensington Court Electric Lighting Company (Limited) to the Board of Trade for a license under the Electric Lighting Act, 1882, to lay down wires for the supply of electricity in streets in the vicinity of Queen's-gate, the Vestry do give their consent to such application so far as regards the area in question, subject, however, to conditions being agreed to by the company similar to those contained in the license above referred to, and provided that, in the event of any general system being hereafter adopted by the Vestry for the laying of mains, &c., the company undertake to change the mains now proposed to be laid in such manner as to conform to and generally to be subject to such future system. All the mains, &c., now proposed to be laid down, to be laid in such part of the roadway or footway, and generally on such conditions and in such mode as may be approved by the Vestry's surveyor.—Mr. Holmes, who thought that if the demands of the deputation were acceded to, it would create a monopoly, moved that the matter be referred back, which was finally carried.

The Late Fire at Messrs. Willans and Robinson's.—The managers of these works, whose machine shops at Thames Ditton were entirely destroyed by fire lately, with all the patterns and templates, have lost no time, says *Industries*, in reorganising the business. With a few exceptions the orders in hand will not be delayed more than two months, and the company is already booking orders largely for delivery early in the summer, when it is hoped that all the engines on order at the time of the fire—upwards of one hundred—will have been finished. That such energetic steps have been taken to repair the disaster is a matter of some importance to the electric lighting industry, which appeared to be threatened with a vexatious check at a busy time. The large engines for the town lighting station of the Bradford Corporation, of above 150 horse-power each, which were ready to receive the dynamos, were unfortunately burnt, so were two 70 horse-power engines, forming a repeat order (through Messrs. Mather and Platt) for the Fine Art Galleries at Leeds. A similar engine, ready to receive a Siemens dynamo, for the Liverpool Electric Supply Company, was burnt, but fortunately a larger set for the same company, giving 1,500 lights, had been sent away shortly before the fire. Two engines for Messrs. L. Clark, Muirhead and Co., for the Pall Mall Electric Light Company, of 210 indicated horse-power each, were burnt, but some other Willans engines for the same station will be finished in time to prevent delay in opening this station. Some 70 horse-power engines, for the Kensington Court Company, were in the erecting shop and escaped; but three engines of 170 horse-power each, making to the order of Messrs. Siemens for an important installation in London, were less fortunate. However, in all cases satisfactory arrangements have been made to fill the orders with the least possible delay. A great number of engines are in hand for the Admiralty, chiefly for lighting the newer classes of vessels, including nearly thirty engines of the size before referred to as of 70 horse-power, and about 40 of smaller sizes. All these are, of course, for direct driving. Amongst them are four large engines for the Royal yachts "Victoria and Albert" and "Osborne," to work at exceedingly low steam pressure. These engines are required to replace other high-speed engines with which the yachts are already fitted.

LIGHTNING CONDUCTORS.—VI.

BY DR. OLIVER LODGE.

(Continued from page 162.)

On the Value of μ which makes Calculation and Experiment best agree.

37. It is an important matter to know what is the true value of the magnetic permeability of iron applicable to these very rapid alternations, and we will see if the last article can help us to an answer.

First, it will be instructive to calculate out the whole circumstances of the experiment of § 25, assuming the value of μ to be 400 for iron wire under the circumstances. The following table (Table I.) shows the result, and it can be compared with the table in Article IV., which gave the results for $\mu = 100$ and $\mu = 2{,}500$.

The meaning of the symbols heading the columns has been already explained, but it may be well to recapitulate. P is the total impedance of a conductor, p is the inertia part, and R the resistance or throttling part of it; n is 2π times the number of times the current alternates in a second; and b is a constant such that $R = b\sqrt{n}$. Its value is $\sqrt{(\frac{1}{2} l \mu r)}$ where l is the conductor, r its ordinary resistance, and μ its magnetic permeability.

In one of the rows of the table the expressions by which these things are calculated, or references to the equation or section where such expressions can be found, are, for convenience, added.

The No. 19 conductor is given a part of the table to itself because it formed a permanent part of the circuit; the other four conductors are alternative-paths, and were successively placed in series with the No. 19 conductor. V being the potential acting in the whole circuit, V_0 is the potential acting in the alternative-path portion. The last column of the table exhibits the ratio of these potentials as obtained by direct measurement of the A and B sparks, for the purpose of comparison with the calculated or theoretical values. I may mention that, by help of Art. V., the values of m and n are now calculated more exactly than they were in Art. IV.

38. Plainly the agreement between theory and experiment is, for this value of μ, not very good. It was much better for $\mu = 100$ if the damping were neglected; but it can hardly be legitimate to neglect the damping.

The agreement was very good with $\mu = 2{,}500$ for the three cases which could be calculated out (*see* table in Art. IV., p. 129). The fourth case was not then worked out, but we ought now to be able to do it by help of Article V. The result is shown in Table II.

Thus the agreement between theory and observation is very close for this fourth case also, if μ be taken as 2,500. This set of experiments seems, therefore, to indicate 2,500 as a probable value for μ. It is surprisingly large.

39. To bring out the effect of different values of μ more clearly I append here a table (Table III.) showing the calculated ratio of potentials, available for the A and the B spark respectively, with different values of μ, namely, with $\mu = 1$, $\mu = 100$, $\mu = 400$, $\mu = 2{,}500$. This table gives not only the theoretical ratio of potential but also its undamped value in each case, and thus clearly exhibits the effect of damping.

There is no doubt but that the largest value of μ gives the best agreement. We must not put too much confidence in the indication of this one set of experiments, but we will remember the hint and proceed to discuss a few earlier observations, recorded before § 25.

We may, however, just notice before leaving that this last table serves to illustrate in a general way the truth of what we reckoned in § 36, viz., that if $\frac{P_0}{p+p_0}$ was less than $\frac{2}{\pi}$ (or ·636), an increase in μ diminishes the ratio $\frac{V}{V_0}$; whereas so soon

as $\frac{P_0}{p+p_0}$ gets up to (or apparently near) $\frac{2}{\pi}$, an increase in μ makes $\frac{V}{V_0}$ increase.

Application of Theory to Previously Recorded Experiments

40. Although in the experiments recorded before § 25 we had not quite complete data for applying theory, inasmuch as the particulars of the jar part of the circuit were not specially noted, yet we can try the estimate of 50 metres which we have already made for its self-induction (§ 19), and see whether anything can be done. This is the more desirable because the experiments comparing a round wire, a ribbon of foil, and a strip of gauze come in this portion of the record (*see* §§ 22 and 23). It is probable that for most of these cases the first approximation alone will serve fairly well, since the resistance of the whole circuit was but small.

Wire v. Ribbon.

Referring back to Art. III., therefore, and using the dimension of wire and foil recorded in § 22, I calculate the self-induction of the piece of No. 12 wire by equation (7) as being 26 metres; which becomes 25 metres if the current keeps to the surface.

For the foil, if the current were distributed uniformly all through it, the self-induction would be

$$L = 4\pi r\left(\log \frac{8r}{\cdot 2656\, b} - 2\right) = 436 \times 3\cdot 10 = 13\cdot 5 \text{ metres};$$

where b is its breadth (6·4 centimetres), its thickness being very small. If the current keeps to the surface, L is a trifle less than this, and if it distributes itself unequally, so as to make L as small as possible, as in practice it will, there will be a further reduction; but its amount I do not quite know how to reckon. So I shall take the self-induction as 25 metres for the wire, and 13 metres for the foil.

Hence, using them as alternative paths, and applying the first approximation, with L assumed 50 metres, we should have:—

$$\frac{V}{V_0} = \frac{L_0}{L+L_0} = \frac{25}{75} \text{ for the wire,}$$

and

$$\frac{13}{63} \text{ for the foil.}$$

Comparing these and similarly made calculations with the observations recorded in §§ 23 and 24, as made with two-gallon jars and various alternative paths, we have the following table, comparing theory and experiment:—

Alternative Path.	$\frac{L_0}{L+L_0}$.	Theoretical B spark between flat plates.	Calculated Length of B spark between knobs used.	Observed Length of B spark.
Circle of No. 12 wire	·333	·500	·53	·55
Ribbon of copper foil	·206	·310	·33	·27
Ribbon of copper gauze ...	—	—	—	·27
Long No. 19 copper wire .	·920	1·38	1·62	1·65
No. 27 iron wire	·925	1·39	1·65	1·68
No. 1 copper wire.....	·886	1·33	1·54	1·63
No. 27 iron wire	·925	1·39	1·65	1·63
No. 18 iron wire	·921	1·38	1·62	1·68
No. 19 copper wire.....	·920	1·38	1·62	1·68

This is not a complete account of the matter, because the experiments recorded in § 24 as having been made with pint jars are omitted. The first approximation by itself shews no reason why the capacity of the jars used should matter; but, experimentally, it did matter somewhat.

The calculated spark-length for the copper foil is too great; probably I have not allowed enough for the freedom of distribution of current inside a ribbon. The real self-induction would be less than what I have reckoned it. The slight discrepancy of the No. 1 copper I see no reason for. The self-induction of the strip of gauze I have not yet reckoned.

Earlier Experiments reduced by help of § 21.—Again, going further back still in the record of experiments to §§ 16 and 17, and reducing the spark-lengths there given to centimetres between flat plates, we have A = 1·87 centimetre, and for B the following numbers:—

Alternative path.	Observed B spark reduced to flat plates.
No. 1 copper	1·66 cm.
„ 27 iron	1·51 „
„ 1 „	1·53 „
„ 19 copper	1·62 „
„ 18 iron	1·53 „
Two gutta-percha leads in concurrent series	1·80 „
„ „ „ in opposing series	1·48 „
„ „ „ in parallel	1·48 „
One lead only	1·48 „
One lead, with the other one closed	1·41 „

Applying the first approximation theory to the No. 1 copper lead, and taking L as 50 metres, we get as the theoretical B spark, for this case, 1·65 centimetre; which agrees with observation. The other leads seem to require the second approximation to bring out their slight differences.

We will now proceed with the record of further experiment.

(To be continued.)

MR. MACKIE'S REPORT ON THE PADDINGTON ELECTRIC LIGHTING SCHEME.

To Frank Dethridge, Esq., Paddington Vestry.

Sir: I herewith enclose for the guidance of your Vestry estimates of cost for electric lighting of the Borough of Paddington, from a central station at the dust yard.

I have given, first, an estimate (A), for lighting by continuous current with underground copper leads for a unit installation of 2,000 16 candle-power incandescent lights; and another (B), for the like unit of 2,000 incandescent lights under the alternating system.

Every installation of 2,000 lights will be remunerative, and, therefore, the central station can comprise as many such units as may be desired to start upon, or be added from time to time.

I also add a third estimate (C), which deals with the portion of the dust yard which is at once available without encroaching on any of the buildings or plant required for the dust work.

This portion (C) I suggest should be used, in the first instance, as a pioneer station, and should form a nucleus at the present time; and in the future, when units of the central station shall have been added, it should still be retained for the same purpose, and for which it was designed, viz., to seek for and supply customers in all directions, and with both incandescents and arc lights. To this end this station (C) has been designed to receive three continuous-current dynamos for 1,000 incandescent lamps each, two continuous-current dynamos for 50 arc lights each, two alternating-current dynamos for 500 incandescent lamps each.

This would be a considerable station in itself and remunerative. The total of incandescent lights would be 4,000, and the number of arc lights 100, for streets and other purposes.

It is to be understood that the reasons for advising this (C) station to be first adopted are:—1. That the site exists and can be appropriated to the purpose; 2. That this (C) station can supply lights to any part of the Borough, however distant, and to isolated customers or small groups of customers; 3. That the outlay will be the least upon which a central station can be based.

The respective costs of the A and B units are:—*a*. Continuous-current system, with copper leads, as marked on map, the cost, including machinery and plant, would be £10,425. 10s. *b*. The alternating-current system, with light overhead wires, would be for machinery and plant £7,019. 12s. 6d., showing a difference of £3,405. 17s. 6d.

In judging of the comparative desirability of the continuous-current system it should be borne in mind, first, that the current is never dangerous; second, that the service is underground; third, that storage batteries can be charged by it; and, fourth, consequently there is an additional very important safeguard against a breakdown, as (fifth) the accumulators can always supply current night and day for a limited time, and therefore (sixth) the engines need only be run on the lighting after dusk or during fogs; or if (seventh) the engines are employed in the daytime in charging batteries of accumulators, an additional number of incandescent lights can be run at night.

The cost of working and maintenance of the (A) continuous-current unit is £4,022. 14s. 3d., of the (B) alternating unit £4,403. 3s. Transforming the total current into cost of 16 candle-

Digitized by Google

power lamps, we have price per hour 0·2207 of a penny, and of the alternating current 0·2416 of a penny. Or in Board of Trade units "1,000 watts" continuous current 3·7519; alternating current 4·1072 of a penny. The price paid by consumers in both cases is 7¼d. Therefore, 2,000 lamps of 16 candle-power, running 2,186 hours, gives 263,320 Board of Trade units at 7¼d., yielding an income of £7,924. 5s. per annum, less expenses of working £4,022. 14s. 3d., leaving a balance of £3,901. 10s. 9d.; or a dividend of about 37 per cent. on the capital outlay.

The objections to the alternating system are:—1. That the current is of such high tension as to be unsafe for use in edifices, or otherwise, without the use of transformers to reduce its tension, before entering the house, to safe limits. 2. The engines must be run night and day, as (3) accumulators cannot be charged by alternating currents, and consequently there is (4) not that safeguard against breakdowns. (5) That arc lights cannot be so well run on alternating currents as on continuous currents, and each arc in street lighting and each group in a building would require a transformer.

The advantage of the alternating-current system is that the current can be carried for any distance by very small and comparatively inexpensive wires. Taking the income as before at £7,924. 5s., and the alternating-current expenses at £4,403. 3s., the balance would be £3,521. 2s., or a dividend of 50 per cent. on the capital outlay. The cost of the proposed C station would be £21,170. The income would be from the 4,000 lamps at 7¼d. per unit £15,583, and 100 arcs at £27 per year £2,700, or a total of £18,283. The expenses would be £10,027. 5s., giving a net profit of £8,255. 15s. on a capital of £21,170, or a dividend of nearly 39 per cent.

In regard to the map accompanying the report, I would observe that the least costly but most effective route for the main electric current leads (continuous current laid underground) has been mapped out, and that this system taps the main thoroughfare of Edgware-road, and the great mass of mansions lying between the Central Station at the dust yard and Hyde Park. This district is well calculated for securing a number of customers, and, consequently, of being a profitable district.

I would, however, observe that the intervention of the Great Western Railway's extensive property between the dust yard Central Station and Westbourne-grove would cause an expenditure of some thousands of pounds for copper leads, if served by continuous current of low tension. But this important district can be very cheaply reached by alternating current and overhead wires, with high-tension current, reducible at customers' residences or shops by transformers. The suggested line of alternate-current mains is shown on the map by a yellow line and dot. I may also remark that the Pioneer Central Station (C) system can be materially strengthened by three sets of storage batteries at, say, the spots marked blue on the map.

It might be well to generally remark here that, as the (C) Pioneer Central Station is designed, a commencement of the permanent underground system is made; and that beyond this provision is otherwise made for supplying any person or any district that may desire it with electric light, the actual cost of length of light-wire mains in each particular case being the only item which cannot be stated in advance, depending, as it does, on the particular circumstances of each case.

No mention has been made in this report of the use of electricity for motive power. The suggested (C) station, however, would be capable of supplying power in the daytime if required, and profit would accrue from this source.

In regard to the powers to be taken by the Vestry under the Act those powers would extend to the whole borough, and all the inhabitants would be entitled to equitable treatment. It would not be needful for the Vestry to incur the outlay and responsibility of extending the electric lighting over the whole area at once. They must, however, state in the provisional order the extent of area they will light in the first year, and how much extension of area they will light in the following three years. Beyond this the extension is purely optional, the Vestry granting on applications from individuals or districts, or refusing if they choose to do, the applicants having power of appealing against injustice to the Board of Trade. If the Vestry wished to restrict their power to a minimum, the work to be done in the *first* year might be the erection of *part* of the (C) station, say the erection of two boilers, two engines, and two alternating dynamos for 1,000 lamps. The work to be done in the following three years might be a portion of the continuous-current system, and of the mains laid down on the map, say the laying of the leads to the South Wharf-road. The remainder of the electric work would be done on application by individuals or districts, and the concurrence of the Vestry therewith.

The Vestry having obtained powers for the whole borough could at any time advance the general works beyond the legal liability incurred in the grant of the provisional order.

Finally, I would say that the estimates given are, in my judgment, ample for covering any probable expenditure, and that if specifications shall be directed by the Vestry at any time hereafter to be prepared, the tenders sent in should be for less amounts. The estimates are all based on the supply of current only by the Vestry; and it is distinctly advised that house and internal fittings be left entirely with the customers, except that in every case the Vestry shall have the approval of the same as being proper and safe for the service.

S. J. Mackie.

LETTERS FOR LEARNERS AND UN-PROFESSIONAL READERS.

BY H. D. WILKINSON.

SECTION II.—ELECTRO-MAGNETIC FIELDS.

(*Continued from page 140.*)

139.—*Electro-Magnetic Induction.*—We shall conclude this section with a consideration of electro-magnetic induction and magnetic permeability, both of which are closely allied to the foregoing subject of magnetisation, and in such constant use in descriptions of, and discussions on, electro-magnetic appliances as to make it important for the student to have a clear conception of their meanings. At the same time, consistently with making the subject intelligible, we shall dwell on it as briefly as possible.

At the outset, the relation which "magnetic induction" bears to "intensity of magnetisation" should be clearly understood. We may state this concisely by saying that intensity of magnetisation is proportional simply to the number of lines of force per unit area passing through the iron *due to its own acquired magnetism*, while magnetic induction is proportional to the number of lines per unit area passing through the iron, due to its own acquired magnetism, *plus those due to the magnetising field.* The latter is the more practically useful means of measurement, since, in practice, we necessarily concern ourselves with the *combined magnetic effect* of the magnetised iron and the electro-magnetic field causing its magnetisation. Recalling what was said in para. 133, it will be remembered that through the mass of any piece of iron which has been magnetised to a strength of pole equal to m C.-G.-S. units, and whose dimensions satisfy the condition of "endlessness," there are $4\pi m$ lines running from pole to pole (south to north). The condition of "endlessness" ensures the absence of any demagnetising lines (running from north to south, or in a contrary direction through the metal) which would make the actual number of lines through such a piece of magnetised iron less than $4\pi m$.

Digitized by Google

Such being the case, we have in a piece of iron of a square centimetres (uniform) cross-section $\frac{4\pi m}{a}$ lines per square centimetre passing through its mass and *due to its own acquired magnetism*. Now, the intensity of magnetisation (I) is found by

$$I = \frac{m}{a},$$

putting which value in the above we find that

$4\pi I$ = lines per sq. cm. due to acquired magnetism;

and, therefore,

$$I = \text{lines per sq. cm. due to acquired magnetism} \times \frac{1}{4\pi}.$$

This proves the statement made above, that the intensity of magnetisation is proportional to the lines of force per square centimetre through the iron, due *alone* to the magnetism acquired. The same fact will have been noticed in the practical examples already detailed, in which the magnetising force of the coil was *subtracted* from the combined magnetic effect of the coil and core together before calculating

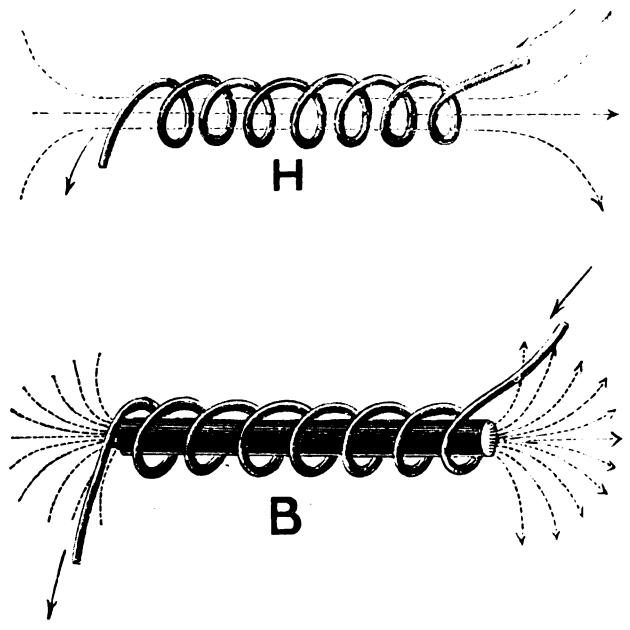

FIG. 121.

the intensity of magnetisation. Similarly, we have seen that the strength of a *permanent* magnet may be expressed in units of intensity of magnetisation, since the term only involves the lines of force due to its own magnetism, or the strength of pole of the magnet *itself;* but the same cannot be expressed in units of magnetic induction, since this term implies the presence of a magnetising force, and must include the value of the same.

Now, to understand what is the precise meaning of magnetic induction, let us take a simple cylindrical coil of wire as at H (Fig. 121). On passing a known current through it, a magnetic field of a definite intensity is set up in its interior. We have then a magnetising coil—that is, one capable of magnetising any magnetic metal placed within it. We have shown that the field intensity in the coil, or, what is the same thing, the lines per square centimetre, can be easily calculated. Suppose there are H lines per square centimetre through the ocil. Now, on putting an iron core inside, as at B, we find that the intensity of field becomes very much stronger than before; in fact, the presence of iron in the coil has enormously increased the number of lines. Now, what is termed "magnetic induction," or sometimes simply "induction," and denoted by the letter B, is the strength of field which exists when the iron is put in—that is, the number of lines per square centimetre. It must be remembered, however, that the part of this field B which we called H existed *before* the iron was put in, and therefore B – H lines have been *created* by adding the iron. We say created because they did not exist in the iron before it was put in the coil, neither did they exist in the coil space before. The lines B – H are therefore those due *alone* to the magnetism acquired by the iron, and these we have found above to be equal to $4\pi I$. We therefore arrive at an equation expressing the fundamental relation between "magnetisation" and "induction," viz.,

$$B - H = 4\pi I,$$

from which, if we know the magnetising force H and the magnetisation I, we can find the induction by

$$B = 4\pi I + H.$$

For example, by inspection of the upper curve in Fig. 119 we find that the magnetisation was 1,280 units for a magnetising force of 54 units. Hence the magnetic induction for this force was

$$4\pi\ 1{,}280 + 54 = 16{,}144 \text{ lines per square centimetre,}$$

of which 54 are due to the magnetising coil and 16,090 to the magnetism acquired by the iron. Working out a few values in the above manner we obtain data to plot a fresh curve (Fig. 122) for the same core, the vertical ordinates being now in C.-C.-S. units of magnetic induction or lines of force per square centimetre through the iron. This shows the connection between induction and magnetisation, and how one may be deduced from the other. It is possible, however, that the student may find some difficulty in conceiving the physical meaning of the

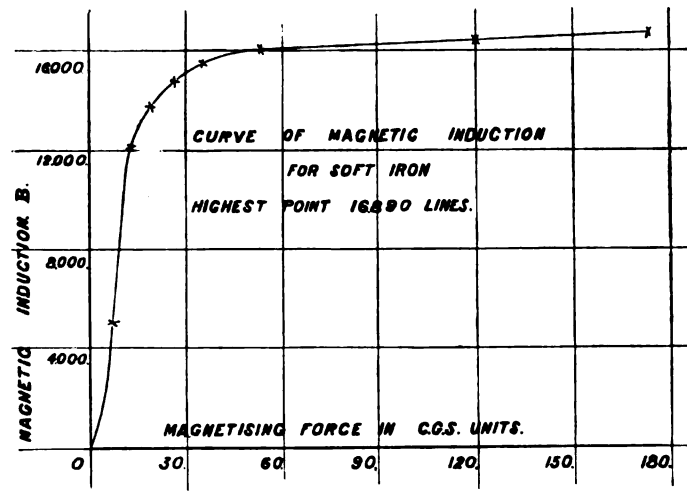

FIG. 122.

formula as applied to the reverse operation, viz., that of deducing the magnetisation from the magnetic induction. From what we have shown above, the formula is evidently :—

$$I = \frac{B - H}{4\pi}.$$

Now, suppose the value of B in a certain *ring* of iron under a given magnetising force H has been ascertained. It is simple enough to put these values into the above formula and so calculate I; but the physical meaning is not so simple to follow, for by I is meant the pole strength per unit area of metal, or moment per unit volume, while the piece of iron under test is ring-shaped, and, therefore, has no poles and no magnetic moment. The explanation is that for a given pole strength per unit area, the mass of the iron is in a certain definite condition magnetically, which can be represented as equivalent to a definite field or number of lines per square centimetre, running through its substance. Now, it is clear that this identical magnetic condition of the iron, as regards the number of lines through it, can exist equally well when the iron forms a closed circuit, and exhibits no polarity at all; indeed, we have already shown that the internal field equivalent to a magnetisation I is represented by $4\pi I$ lines, and therefore the formula is quite intelligible. With a ring-shaped iron core the magnetisation cannot be determined by a magnetometer, as there are no poles

Digitized by Google

to act on the needle, but it can be calculated in the above way from a direct experimental determination of the magnetic induction.

140. *Practical and Asbolute Magnetic Saturation.*—It will be noticed in the above curve that magnetic induction in the iron, up to 12,000 lines, takes place very rapidly under the action of 10 or 12 C.-G.-S. units of magnetising force, and that as the force is increased beyond this point induction occurs more slowly. For instance, double the force (24 units) only produces 14,700 lines, or an increase of a little over one-fifth the field. Again, three times the force (36 units) only produces 15,700 lines, or an increase of about one-third the field. And it will be seen by the curve that any further increase in the force produces but slight increase in the induction; in fact, for practical purposes, it would be very uneconomical to expend 180 units of magnetising force to produce 16,900 lines, when 16,000 could be produced with less than one-quarter the force. It is for this reason that the top bend of the curve just before it becomes almost horizontal is taken as the practical limit of saturation, and in soft iron may be taken as about 16,000 lines.

In the best quality of iron now obtainable, such as Swedish charcoal iron or well-annealed wrought iron, the induction curve rises quicker, and reaches considerably higher values. For dynamo armatures built with iron of this quality a fair average saturation met with in good machines ranges from about 18,000 to 20,000 C.-G.-S. lines, or sometimes higher. The point of "absolute saturation" is of purely theoretical value, and, of course, means the point at which the curve ceases altogether to rise. It would appear that there could be no absolute saturation point for magnetic induction, because the magnetising force is one of its constituents, and it would, therefore, seem probable that induction would always increase with

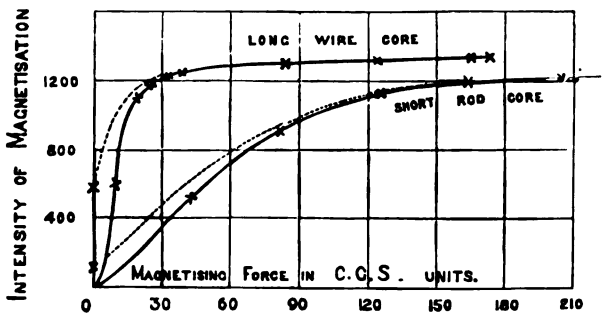

FIG. 119.

an increase in magnetising force. To determine this question evidently requires the employment of exceedingly high magnetising forces, to obtain which the magnetising coil, as applied directly to the specimen of iron under test, is out of the question. The researches of Prof. J. A. Ewing and Mr. William Low in this direction furnish by far the most advanced experimental data on the subject, inasmuch as these able observers have for some time brought to bear upon the specimens of iron under test far higher magnetising forces than have been hitherto employed. Their method consists in placing the piece of iron under test between the poles of a powerful electro-magnet, so as to form a complete magnetic circuit, and thus force a large number of lines through it. To increase the density of lines through the test piece it is thinned at the centre by turning down to a very small diameter, while its two sides extend outwards, cone-like, to fit the pole-pieces. This gives the test piece the shape of a reel or bobbin, of which the thin central portion is called the neck. By this means, as communicated to the Royal Society in their recent Paper (November 22, 1888), the authors have forced the magnetic induction in wrought iron to the enormous value of 45,350 C.-G.-S. units, and in cast iron to 31,760, and find that there is no appearance of a limit to the extent to which magnetic induction may be raised. To show what an advance this is, a remark of Drs. J. and E. Hopkinson in their able Paper on Dynamo-Electric Machines in 1886 *(Phil Trans.)*, may be quoted, "No published experiments exist giving the magnetising force required to produce the induction here observed in the armature core amounting to a maximum of 20,000 per square centimetre."

The direct measurement of the induction was made in the usual way; the central neck, where the induction is greatest, was wound with a coil of wire connected to a ballistic galvanometer, and the "swing" on the latter observed when the iron bobbin was turned round through half a revolution, so as to face the opposite poles of the electro-magnet. As this completely reverses the direction of magnetisation, the deflection is proportional to twice the induction in the bobbin. We shall refer again to the ballistic galvanometer and the method of calibrating it in absolute units by the use of earth-coils. The measurement of the exact value of the magnetising force (necessary in order to calculate the intensity of magnetisation) was attended with great difficulty, and it was not until the Paper referred to above that the authors were able to speak with confidence of its determination. The method was to wind a second coil at a certain measured distance concentrically round the first, and to subtract the deflection obtained with the first coil from that obtained with the second, the difference being proportional to the field within the air space between the two coils. To investigate how nearly this field approximated to the magnetising force acting on the metal, was a determination of great difficulty, but the authors say in the above Paper that by modifying the form of the cone-shaped sides of the iron bobbin a uniform field was obtained in the central neck, and the magnetising force within the neck was sensibly the same as that in the air immediately around it.

Having established the correctness of the determinations of the magnetising forces employed it was found that for wrought iron the intensity of magnetisation remained stationary at 1,700 C.-G.-S. units, while the magnetising force was varied between the enormous values of 2,000 to 20,000 C.-G.-S. units, showing that apparently a point of "absolute" saturation as regards magnetisation may be reached. This saturation point for cast iron is found by the authors to be 1,240 units. The point of "practical" saturation for soft iron will be seen by the curve obtained above experimentally (Fig. 119) to be about 1,300 C.-G.-S. units.

(To be continued.)

NEW CATALOGUE OF THE GENERAL ELECTRIC COMPANY.

Messrs. Binswanger and Co., who trade under the above title, have just issued a catalogue of electric lighting plant and material which is probably the most complete and exhaustive list of electric lighting apparatus which has yet been issued; every possible requirement, from a one shilling cut-out to a 100 horse-power engine, is to be found within these pages. The book is of quarto size, and consists of 80 pages of closely printed matter, with nearly 300 woodcuts, most of which are new. It is evident that special regard has been had to the requirements of the trade which is now springing up in connection with central station lighting. An increasing number of non-electrical firms are now engaged in the wiring and fitting of houses, and for this class the information here contained will prove invaluable. Under general headings the following articles are catalogued:—Switches, cables, lamps and holders, cut-outs, electricity and potential meters, glassware, brass and other fittings, arc lamps and carbons, list of various dynamos and motors, accumulators, engines, insulators, and various sundries and estimates. The whole of the switches and cut-outs supplied by this company are mounted on porcelain bases, as recommended by the fire insurance offices, and the designs are of a safe and substantial description. Much attention has evidently been given to the design of electroliers and glass fittings, many of which are of very beautiful character. We are glad to observe that an effort has been made to reduce all screws and tubes to standard sizes. It is also satisfactory to note that there is a decided tendency to a reduction in price, especially of small fittings, compared with those which were ruling a year or two ago. We strongly recommend our readers who are interested to endeavour to secure a copy of this valuable work.

The rates for the United Kingdom remain as follows:—	5 0	10 0	19 6

TO ADVERTISERS.

"The Electrician" offers exceptional advantages to Advertisers. **It has the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to this office.

Trade Advertisements *intended for the current issue must be handed in not later than First Post on Thursday morning.*

Small Prepaid Advertisements *(for Rates see page xi.) are accepted up to 4:30 p.m. on Thursday.*

TECHNICAL PRINTING.

"The Electrician" Printing and Publishing Company (Limited) *beg to inform Electricians and Electric Light Engineers that they make a specialty of Technical Printing, and have a Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electrical Catalogues and Electro-Technical Literature generally.*

The Electricians' Directory.

Royal 8vo. Cloth Boards, 3s. 6d., post free 4s.

At the commencement of each year is issued The Electricians' Directory and Handbook. *The Directory was established in 1883, and has now attained considerable proportions. Every care is taken to make the names and addresses of all persons engaged in the Electrical Industries absolutely accurate. Useful Tables and Electrical Formulæ are given, together with popularly-written Biographical Notices of the leading Electricians, accompanied in many cases by Portraits.*

THE DIRECTORY FOR 1889 IS IN PREPARATION.

VOLUME XXI. OF "THE ELECTRICIAN."

Volume XXI. of "The Electrician" is NOW READY,

Price 12/6, post free 13/6.

NOTICE.

It has been found necessary to defer the publication of the Portrait of SIR WILLIAM THOMSON, announced in our last issue, until next month.

ELECTION OR NOMINATION?

It will be seen from our report of its last week's proceedings that the Society of Telegraph-Engineers and Electricians enlivened the period of suspense while the votes were being counted by debating whether in future the annual vacancies on the Council shall be filled by nominees of the Council who are in office, or be elected by the members of the Society at large. This, at all events, is the issue that was raised, although in springing the motion upon the meeting unexpectedly the mover did not state it in those blunt terms. Fortunately a decisive vote was not taken upon the subject, but was postponed to give time for further consideration. The act of submitting the question to the members present was a virtual confession that they had a right to be consulted, and to have taken their vote upon it without notice would have been in the highest degree impolitic. Had the Council simply reverted to their former practice of naming only a sufficient number to fill the current vacancies, and if called to account professed their inability to name more than that number, or their deliberate conviction that to have done so would have been injurious to the welfare of the Society, something might have been said for such a course. But for the course actually pursued hardly anything can be said, unless, perhaps, it may be taken as an indication that the Council itself is not unanimous on the subject, and by way of compromise has allowed it to be brought before the members as an open question.

Taking this view of the situation, it will be only fair to allow those who are most intimately asssociated with the management, and responsible for its efficiency, to have their say, and to do their utmost to persuade the members to forego the privilege which they have exercised at the last three or four annual elections. Mr. Preece said a good deal that was cogent for his view of the case, but spoiled it somewhat by saying too much. It is idle to tell the members that they can dismiss the Council if it does not discharge its functions properly. For some

Digitized by Google

flagrant misconduct, which it will never be guilty of, possibly the Council might be got rid of; but in the matter under discussion that body is already unassailable, and the proposition now put forward would tend to make it still more so. Of course members of the Society—that is to say, the present electorate—will take this fact into account in forming their final judgment, as well as the *pros* and *cons* of the case as submitted to them by the Society's executive. But this is not all; they will have to seriously consider whether the members themselves have shown, or are ever likely to show, such warm interest in the election of the Council as to combine or agree upon a "ticket," as the Americans say, or list of names from which a choice is to be made. If the members will not do this, the Council must; and our own belief is that what the former desire is not so much to take away the nominations from the Council as to retain the right to vote upon them.

From what has been said above it will be seen that the actual privilege exercised by members is neither very considerable nor very valuable, and that, consequently, the loss of it would not be a very grievous hardship. But there is one hardship which no man of sense cares to submit to, namely, that of having to go through an empty and meaningless formality. It was this that led to the so-called "agitation" resulting in the present mode of election, which it is now proposed to abandon. If we are not mistaken the original method was the same as it is now, but it drifted into the one which Mr. PREECE wishes again to fall back upon. For some years previous to the "house list" being extended the election was a spectacle only fit to provoke laughter. A few unsophisticated members in the country sent up their papers by post; a few others, chiefly new intrants, crept sheepishly down the gangway and discharged their solemn functions in the well of the theatre. When the neighbouring clock-tower chimed the fatal half-hour, the sacred urns were carried away by the scrutineers, while the audience tried to screw their countenances into an appropriate semblance of anxiety. Presently, and before Big Ben can strike the full hour of nine, the result is silently conveyed to the Secretary, who, with a gravity for which we hope he will one day be rewarded, announces that Professor This and Doctor That are the gentlemen who have been duly elected. He might have said unduly with greater truth; for a more unnecessary and undue ceremony could hardly be conceived. If this is an election, then eggs may be said to elect their sitting hens, and Churchmen their Episcopal rulers.

The excuse put forward by the Council of the Society is that to nominate more candidates than are required leads to heart-burnings and needless humiliations. So far as it concerns the Council, the argument is good, but not as concerns the members. To be officially invited by the governing body of the Society to stand for election is indeed vexatious if it ends in being rejected by the members. Nobody cares to be set up as a nine-pin for people to shy at, especially when five out of nine are bound to be knocked over. It would be different, however, if the nominations were the members' own; and whether by circular letter inviting their recommendations, or by general meeting to receive them verbally, such a method of ascertaining the preference of the electorate has much to recommend it. It would have the merit at once of leaving the members no room for complaint, and the Council still plenty of room for nominating their own men with a tolerable certainty of their being elected—freely as well as duly.

Of course we are offering these suggestions only on the assumption that the question, having been raised, will have to be adjusted between the Council on the one hand and the Members on the other. We fancy it would have been wiser not to have raised it at all. But as matters have taken this turn, they will be settled probably by some sort of compromise more or less resembling those we have hinted at. One other may be mentioned here in conclusion. The election of Associate Members is not precisely on the same footing as that of Ordinary Members, and it might be possible for the Council to name more than the requisite complement of Associates, while refraining from naming more than the complement of Members, without giving occasion for personal offence which the Council is so anxious to avoid. There is plenty of time, however, to think these details carefully over. What the Council have to bear in mind is that the members do strongly object to play at make-believe in registering a foregone conclusion which goes by the name of an Election. On the other hand, what the electors have to remember is that a delicate and onerous task, if it devolves upon them, is still more delicate and onerous when it falls upon the Council; and, further, that in the present mode of election, with which they are satisfied, the electors do nothing but reject or accept the Council's nominations, initiating none among themselves. They certainly ought to be allowed sufficient time to try; and the Council could not do better than to give them the opportunity and see what would come of it.

THE SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.

ANNUAL GENERAL MEETING.

The annual meeting of this Society was held at the Institution of Civil Engineers, on Thursday, 13th inst., Mr. Edward Graves in the chair.

The SECRETARY (Mr. Webb) reported the death of M. Gaulard, who died on the 22nd of last month.

The CHAIRMAN said he was sure that he was expressing the feelings of all the members present when he gave expression to their most sincere regret at the death of M. Gaulard, who for many years was the special apostle of the new system of electric lighting. He lived to see many people adhere to his views, but he unfortunately died before reaping the practical advantages accruing from his inventions.

The SECRETARY (Mr. Webb) read the

REPORT OF THE COUNCIL,

as follows:—

"The Council have satisfaction in reporting that the number of new members elected into the Society during the present year considerably exceeds the average, including 19 foreign members, 9 members, 104 associates, and 36 students, or a total of 168; and 35 candidates have been approved for ballot at the first meeting next month. Sixteen associates have been transferred to the class of members, and 16 students to the class of associates. The number of deaths, although not quite so great as last year, has been considerable. We have been thus deprived of five foreign members, Senor Ugarte, Inspector-General of Telegraphs at Buenos Ayres; M. Jules Raynaud, of the French Telegraph Administration, whose death took place under lamentable circumstances; Mr. L. Bigelow Jones, of Cordareille, Mass., U.S.A.; M. Gustave Cabanellas, the well-known French writer on electrical subjects; and Don José Rodriquez Vera, of the Spanish Government Telegraphs. Seven members, including our late president, Sir Charles Bright, whose services in nearly every branch of electrical engineering, but more especially in connection with land and submarine telegraphs, are well known; Mr. Thomas Russell Crampton, who was intimately connected with the first successful submarine line, and was eminent also as a civil and mechanical engineer; and M. Gaulard, whose name must always remain identified with the transformer system of electrical distribution. Eight associates—amongst whom are Mr. George Mason, manager of the Telephone Construction and Maintenance Company; and Mr. George Henley, of the Henley Telegraph Works Company—four foreign members, nine members and 14 associates have retired from the Society during the year.

"The general meetings of the Society, which by the liberality of the Institution of Civil Engineers continues to be held in the lecture hall of the Institution, have been seventeen in number, inclusive of four extra meetings; and the Council have arranged, by the kind permission of the Institution, to hold next year sixteen meetings on fixed dates, and, should occasion arise, one extra meeting.

"The average attendance is increasing considerably, and the Papers read during the season have, as usual, ranged over a variety of subjects, as will be seen by the subjoined list, and have in most cases given rise to important discussions.

[The Papers and discussions have appeared in *The Electrician*.]

"The Council have awarded the Society's annual premiums in respect of Papers read during the twelve months ending the 31st May last, as follows:—The Society premium, value £10, to Prof. Silvanus P. Thompson, member, for his Paper entitled 'The Influence Machine from 1788 to 1888;' the Paris Electrical Exhibition premium, value £5, to Mr. A. C.

Digitized by Google

Cockburn, member, for his Paper on 'Safety Fuses for Electric Light Circuits, and on the Behaviour of Various Metals usually Employed for their Construction;' the Fahie premium, value £5, to Mr. Edward Stallibrass, member, for his Paper on 'Deep-Sea Sounding in connection with Deep-Sea Telegraphy.'

The Council desire further to highly commend the original communication by Mr. E. O. Walker on 'Earth Currents in India,' published in Part 71 of the *Journal*, and which is practically a continuation of previous valuable communications on the same subject contributed by that gentleman.

"With the view of inducing those who take part in discussions at the Society's meetings to condense their remarks as far as practicable, and with the further object of affording more opportunities to the younger members of joining in the discussions, the Council have introduced the following rule, which, so far, appears to have met with the approval of the members generally, viz., 'That when a speaker shall have occupied ten minutes the chairman shall sound a bell, and if the speaker do not close his remarks within the next two minutes the question shall be put to the meeting whether or not he shall be permitted to continue them; but the chairman shall have authority to suspend the rule on exceptional occasions.'

"The Committee on Electrical Nomenclature and Notation have prepared a draft report, which has been carefully considered, but it is not yet sufficiently advanced to be submitted to the full committee for final approval.

"The committee appointed to revise the rules and regulations issued by the Society in 1883 for the prevention of risks of fire arising from electric lighting, hoped to have been instrumental in bringing about the general adoption and recognition by all the fire insurance offices of one set of rules, to be modified from time to time as occasion required, by which much inconvenience, both to the offices and to electrical engineers and contractors would, in the opinion of your Council, be avoided. In the endeavour to effect that desirable object they were warmly seconded by the Fire Offices' Committee; but owing to the attitude taken up by at least one of the leading offices, the Committee of the Society found themselves compelled to limit their recommendation to a revision and amplification of the general rules of 1883, leaving the insurance offices to issue such other rules of a more detailed nature as they might think fit.

"Her Majesty's Government having decided to take no official part in the forthcoming Universal Exhibition at Paris, the Society was requested by M. Berger, the Director-General, to place itself at the head of the movement being made to induce the representatives of electrical science and industry in this country to take part in the Exhibition, and practically to take charge of that section.

"Your Council consented, as a preliminary step, to ascertain how far British electric manufacturers were likely to become exhibitors, and accordingly appointed a committee for that purpose, it being understood that upon the result of their inquiries must depend whether the Society would be justified in undertaking the functions which the Director-General desired them to fulfil.

"The response to the Committee's circular, which was widely distributed, was so unsatisfactory that the Council were compelled to decline M. Berger's request.

"The President of the Society and several members of your Council have been nominated on a committee called the Mansion House Committee of the 1889 Paris Exhibition, of which the Lord Mayor is the president, and formed to watch the interests of British exhibitors generally, and such of those who purpose to exhibit in the electrical section are sure to be cared for.

"The Council are glad to report that the class of students continues to increase in numbers, and that all the students' meetings have not this year been so largely confined as last year to the discussion of Papers read and already discussed at the general meetings, but have included the reading of several original Papers of considerable merit. The necessity for further library accommodation has been felt for some years, and has at length compelled the Council to rent an additional room on the same floor as those already occupied by the Society. Two new book-cases have been purchased, and two others have been most kindly presented by our member, Sir David Salomons. The shelf space thus provided will, it is hoped, meet the increasing requirements for some years to come.

"The financial position of the Society continues sound; but the additional expenditure involved by the increased number of meetings, the corresponding increase in the amount of printed matter in the *Journal*, and by its publication and issue at more frequent intervals, together with the rent of the new room, and purchase of bookcases and furniture, will, it is expected, be found to have absorbed the increase of revenue arising from the large number of new members elected during the year.

"Since the last annual general meeting two *conversaziones* have taken place; one given by our lamented late President, Sir Charles Bright, on the 18th of December last, and one by our present President, Mr. Edward Graves, on the 15th of July last. Both of these *réunions* were held in the galleries of the Royal Institute of Painters in Piccadilly, and were largely attended.

"The replies received to the circular issued by the Council in February last, for the purpose of gauging the opinions of members of all classes as to the proposal to change the name of the Society fully bore out the expectations of the Council, having practically amounted to a unanimous approval. The necessary legal steps have therefore been taken to enable the Society to assume, on the first of next month, its new title of 'The Institution of Electrical Engineers.'"

The adoption of the report was moved by Sir DAVID SALOMONS, and seconded by Mr. CROOKES.

The usual votes of thanks were then moved and seconded to the Institution of Civil Engineers for their hospitality; to the local Hon. Secretaries and Treasurers abroad; to Mr. Graves, as Treasurer; to Messrs. J. Wagstaff Blundell and F. C. Danvers as Hon. Auditors, and to Messrs. Wilson, Bristows and Carpmael as Hon. Solicitors.

The PRESIDENT then announced that they would resume the adjourned discussion of Mr. Edmunds' Paper on

"A System of Electrical Distribution."

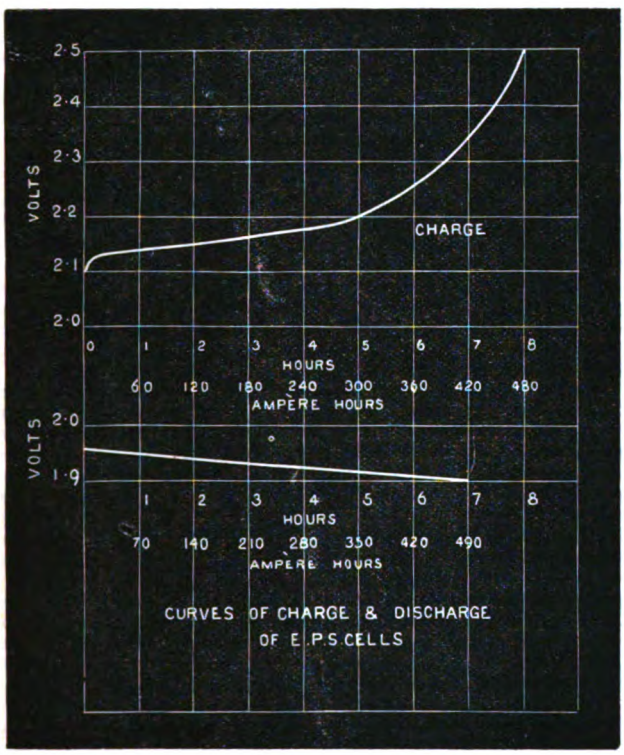
Mr. MORDEY: The meter which Mr. Edmunds proposes to use appears from the description simply to add up the number of charges received by the cells in a given time. This writer did not, so far as he understood the author, take any note of any loss that might occur on the line or in the cells, and in the event of the people at the station supplying, say, 50 or 60 amperes instead of 70, it appeared that the meter still charged the customer for 70 amperes. What safeguard had the consumer that the meter really measured anything? No doubt some check was provided.

Mr. EDMUNDS, in reply, said: Since reading my Paper on Electrical Distribution I have carefully considered the discussion thereon, and also noted the various comments of the technical journals. It has occurred to me that I did not give sufficient data in order to make the system fully understood. Mr. Mordey's question is one that shows that, and I will answer that question first. The arrangement that we use for metering is a solenoid, through which the current passes when it comes from the charging main into the batteries. But this solenoid is so weighted that if anything but a 70-ampere current goes in it does not respond. The consequence is that if the station sends out 60 amperes they do not have any record, whilst if they send out more it is at their own loss. Mr. Mordey says that it is hardly fair to charge for what goes out; but that can be got over by charging a fairly low rate per unit, say 6d. per unit. I claim for the system something more than a set of complicated mechanical devices for attaining certain ends which might be attained by much simpler means, or might be shown to be unnecessary. Therefore, if you will allow me, I will not merely reply to the several questions raised, but will add something to my previous remarks, in order to make you more intimately acquainted with the subject. If, therefore, in this reply I should either repeat myself, or give you obvious or well-known information, I must beg you to excuse this on the grounds that I wish to be fully understood. I have decided to reply to the several speakers as a whole rather than in detail. First, let me express my thanks for the recognition accorded by the members to the ingenuity of the scheme, for such recognition is most encouraging, and is one of the most valuable recompenses one can obtain. I also appreciate the various suggestions made as to the desirability of simplifying the details, and removing unnecessary parts. I think that there was a feeling at the last meeting that the machine was fearfully and wonderfully made. I am glad to say that since I was here I have entirely remodelled the apparatus, and instead of the 32 contacts we have now only eight, and it now occupies a space of less than 18 by 12 by 7½, and instead of costing about £25 to make, they ought to be produced at less than half that sum (applause); in fact, instead of being an experimental model it is a practical working instrument. What is still more important, the new instrument, being free from all springs and cams, it can never, under any circumstances, open the circuit and cause the light to go out. All the changes are made by giving an alternative path to the current through the cells or through a suitable resistance. I think that Mr. Reckenzaun considered that the fumes of gases evolved from the cells were rather harmful to an arrangement of that kind, but by placing over the cells a solid paraffin cover, I find that we do not evolve gases. The hydrogen gas comes off very slightly, and is discharged as a bubble; and although charging with a current of 70 amperes, and carrying on a charge for 24 hours, and bringing up the batteries to a high point of charge, we have not any great amount of gas liberated. Now comes the question as to the necessary charging potential. I said in my Paper that we could charge cells intermittently to their full charge with a mean voltage per cell of 2·25, instead of a constant 2·5 volts per cell as is required where cells are charged continuously, and I wish to explain this, and to show why this differs from ordinary practice alluded to by Mr. Reckenzaun. In the first place, I said a mean or average voltage, and not a constant potential. We have a constant current of 70 amperes, and that is our only constant. The charging potential varies with the change in counter E.M.F. in the cells, due, as Mr. Reckenzaun points out, to the hydrogen gas in a nearly fully-charged cell on the negative plate giving a fictitious electromotive force. But these are the very points of difference between ordinary practice, such as Mr. Reckenzaun refers to, and the system employed here. Let us try and disabuse our minds about a fully-charged cell as ordinarily understood, which would mean a condition where, after many hours' *continuous* (not intermittent) charging, we get in a set of cells a counter E.M.F. while being charged of, say, 2·5 volts or more, this being the point when it is usual to consider a cell as fully charged, and then we cease charging. If we take this diagram here [hanging on the wall] I will explain what I mean. I believe the practice is to charge the cell for a given number of hours, as is shown, with a 60-ampere current. After charging for one hour you find a rise of the potential at the terminals of the cell from about 2 volts to about 2·15; then as you go on charging it continues practically constant until you come up to 2·2 volts, but that is when you have got five hours into the battery, or 300 amperes. Since I was here I have tried an experiment. I took cells and charged them intermittently. I found that by giving a cell a two minutes' charge—I took the potential of the cell previous to conveying it to the charging circuit—and found 2 volts. When I put them into the charging circuit with 70-ampere current, I found a rise from 2 volts to 2·1, but in two minutes I had only got from 2·1 to 2·2. Now, if I continue the charging—I am speaking of the cell with 300 amperes in it—beyond two minutes I find the cells have a tendency to gas, and then we get a fictitious E.M.F., but if we discontinue the charge at the end of two minutes we have been enabled to pass that in at a charging potential of 2·2. I can add these increments of charge, and I can bring the total ampere-hours into my cells as a whole in 24 hours in the way in which we desire, and yet never have a charging potential of more than 2·25 volts.

But now comes the question. To what point do we charge them? How much energy can we get into them, and how much can we get back again?

Digitized by Google

What are the dimensions of the charging station plant, and what does it cost to operate this system? With regard to the charge in the cells, Mr. Bate remarked that the cells would have to be very much larger than would be necessary if the batteries were allowed to discharge at their full rate, and then replaced by others of equal capacity, by which means we could get twelve hours' charge and discharge, whereas here we could get only six hours' charge out of twenty-four. If Mr. Bate's conclusions were correct, I certainly should not feel justified in taking up your time in bringing such a system to your notice; and here again I feel that fuller explanation is necessary, and I will, therefore, take an example of what we would do in actual practice. Suppose we determined on only having 2,000 volts potential at our station and a 70-ampere current. This would represent 140,000 watts. We can use in our station six dynamos, each giving 400 volts by 70 amperes, and each driven by a separate engine. This would provide an ample margin of power, allowing us to use a ten-mile circuit, which would demand an additional 300 volts, bringing up a total voltage of 2,300 volts. In addition to this plant we should have two spare engines and two spare dynamos, making, in all, eight dynamos and eight engines. We should also provide four boilers, leaving one over as a reserve. Now, let us consider what we can do with such an amount of plant in the central station, and see how many batteries we can charge on circuit. This will give us some indications of the value of the system on a large scale. We can divide our 3,600 cells, so that they can supply 112 centres. Each centre would be capable of supplying current locally of 48 volts by 70 amperes for eight hours, provided the station were run for 24 hours. This would practically enable us to maintain at each of these centres seventy 16 candle-power lamps, or a total of 7,840 16 candle-power lamps on an extended circuit of 10 miles, divided over 112 places.



Now, what would such a plant cost, and what would the running expenses be? Also, what would be the scale of profit? This, I think, is a most important feature for consideration in such a Paper as this, and I am glad to say that I am prepared with figures from actual experience on this point. From first-class contractors I learn that we can have our eight dynamos, eight 50 horse-power engines, four 100 horse-power boilers, and the preparation of the building, the instruments, and ten miles of circuit with the wiring necessary for the fitting in the houses, and the sundries included in the station and on the circuit, for £12,000. In addition to this our 3,600 batteries, taken at the list price of £6 each, would come to the large item in batteries of £21,600. Our 112 distributors, one at each centre, say at £10 each, would come to £1,120. The erection of batteries would cost the company, say, another £1,000; but the consumer would in most cases be asked to supply a room, and, at any rate, pay for the fitting up of the batteries, so that these need not be charged wholly to the supply company. This would give us a grand total of £35,720. Now, let us see what it would cost to run this station at 24 hours a day for 365 days in the year with these engines and these dynamos and the three boilers running continuously day and night, so that practically we should be taking the outside and maximum cost that this plant could represent. We will allow per horse-power 4lb. of coal, which at 240 horse-power for 24 hours a day and 20s. a ton, gives us a total of £3,756 for fuel. We will then take oil and waste at 6s. 6d. per night, which would give us £119. Take the water at 1s. per 1,000 gallons, that would give a total of £300. We will allow for wages £,1,565. We will take rent and taxes at, say, £500, and those items will give us an annual expenditure of £6,240—that is to say, if we run this station without any regard to the demand for 24 hours in a day or the whole year. Now, we will say that we get a revenue of sixpence per unit of the current passing into the batteries, which by the system of metering proposed we could ask. This would give us on the output of such a station a gross revenue of £84 per day, or £30,660 per annum. But such a revenue would only be obtained if the total amount of energy in this station were consumed for eight hours per day throughout the year. I have therefore made a calculation as to the revenue accruing from a less consumption than this. We will take, for example, an average of only one hour per day in the year for the output of the station. That would give us a revenue of £3,832. 10s., and for four hours per day this figure would be £15,330; and this latter is probably about the average throughout the year that we could depend upon. This would only necessitate the station working for an average of 12 hours per day instead of 24, in which case we should cut down the fuel charge one-half, reducing that to £2,000, and our wages might be reduced by one-third, leaving that item at £1,000, and the rent remaining the same would give us a gross cost for running of £3,500 per annum on a gross revenue of £15,330, leaving us £12,000 to the good. This, however, would be by no means all profit, as we must now allow for the depreciation of the machinery and batteries. It is usual to write off 10 per cent for machinery, which for our engines, dynamos, and boilers would be £600. The depreciation of the batteries is more of an unknown quantity. My own idea is that 10 per cent. per annum ought to cover these, but we will put it at 15 per cent.—£3,240, which is a liberal depreciation. This would leave us a gross profit of £7,990 on the supply of current for an average of four hours per day. Placing the capital at £40,000 this would give us a profit of 20 per cent., and this, I think, is a most attractive feature in the system (laughter). Of course, it is often said that figures could be made to prove anything, but I think I have dealt very liberally with all the cost of the plant and the depreciation, and should we increase the demand from an average of four hour hours per day you will understand that the profits mount up very rapidly. This is the best reply that I could make to Mr. Bate and to other gentlemen who made similar remarks.

Mr. Preece and Mr. Bate thought that the proposition to run an engine without a governor was a novel one, but I can assure them that there is no difficulty in achieving this in practice. Nor do we pay too heavily in our coal bill, as Mr. Kapp feared we might, for I find that in our high-speed engines actually in use, instead of the coal being 4lbs. per horse-power we use in practice about 3lbs. to evaporate about 30lbs. of water. We get over the difficulty of slow speed by having a suitable number of small engines, and the E.M.F. required to charge the ten-mile line being about 300 volts, we can always ensure our engines, as we arrange them, running at least at 150 revolutions per minute. We have not found in practice that any difficulties have occurred in this direction.

Prof. Forbes raised a question about lamps having 2½ watts efficiency. I remarked *about* 2½ watts. I did not say that it was actually 2½ watts. I find on investigation that with an actual 2½ watts they blacken too soon, and though the filaments last 1,000 hours, the lamps are not so useful, owing to the blackening and higher resistance, for more than 400 or 500 hours. But if we can take them at 2·7 or 2·75, with a perfectly constant potential, so that we do not overstep the mark even for a short time, we can safely rely upon the lamps coming up to their 1,000 hours. I find that a very slight difference in temperature when working at this high potential is enough to cause all the difference between length or shortness of life in the lamp, and therefore, with such a system as the one contemplated, it is important to know that we can depend upon a certain potential which is practically constant at all times.

Several allusions were made to the undesirability of introducing motor generators into this system. I do not think that they are essential, but I think that they form valuable auxiliaries, and I think it is well to look to the absorption of more current from the charging station by means of motor generators and electro-motors, than would be taken by the demand on the batteries in order to increase our revenues. Further, the cost of batteries is the most heavy one in this system, and although we have enormous advantages when they are going to be used to their full capacity, yet, should we have to meet a large demand for a very short time, it would probably be better to have a small number of batteries, with the auxiliary of a motor generator, than to have the larger number, with their interest and depreciation going on, and which interest and depreciation could not be equal to the revenue accruing from them. That is why I deemed it desirable to have an auxiliary of this kind, but it is only an auxiliary, and not a necessary part of the system.

The important features of my system are the reduction and simplification of the plant in the charging station, not necessitating that the engines should be running all the time at an absolutely constant speed, and requiring the particular attention such conditions demand. The reduction of the potential at the charging station to a point not exceeding 2,000 volts, which, as we have seen, is sufficient with a 70-ampere current to supply an eight hours' demand of 8,000 sixteen-candle-power lamps on a 10-mile circuit. Or, by increasing the batteries and running on a double line (or, as I suggested last time, in the alternative method, where the charging station is to supply four hours' discharge, which is the amount we have based our revenue upon) would allow double the amount of work in a 24 hours' run at the station, thus giving us 16,000 lamps. All those points are very desirable in the interests of economy and safety. The absence also of any high potential on the local lines of the system is a feature of great importance, getting over the vexed question of highly insulated wire. The assurance that, even should there be an accident at the station, or an interruption of the line, there is always a reserve throughout the entire system, and the bringing of the local batteries near to their work, thus considerably reducing the cost of mains, all point to the commercial as well as to the electrical and mechanical advantages of this system. I think that I have now probably answered all the questions that I was asked, but I shall be glad to reply to any further ones (applause).

The PRESIDENT, in moving a vote of thanks, said that the Paper was more especially notable for this, that Mr. Edmunds, in the interval that had elapsed since his Paper was read, had shown that he appreciated the value of the criticisms passed upon it, and he had accepted them to such an extent that he had actually reduced the cost of his apparatus by one-half. That showed the practical advantage of adjourning the reply, and perhaps in future they might follow this precedent to a large extent (laughter).

PROPOSED ALTERATION IN THE METHOD OF ELECTING THE COUNCIL.

The PRESIDENT said that Mr. Preece was burning with a desire to express his views on a matter that was of great interest to the members of the Society.

Mr. PREECE said he wished to call attention to the present method of electing the Council of the Society. It was the custom at one time for the Council to submit a list of those whom they recommended for election, and this was a practice followed by nearly every learned society, including the Royal Society, the Society of Arts, and the Physical Society. There was an exception, however, in the case of their own parent society, namely, the Institution of Civil Engineers, whose practice it was to submit a long house list, which comprised not only the names of the existing Council who were eligible for re-election, but also the names of many others whom the Council held to be sufficiently eminent to be elevated to the executive, and whom they left to the members to elect. In their own Society, owing to a little agitation that had originated in that room at the annual meeting, it was suggested that the members had not sufficient choice or sufficient voice in the selection of those who were to represent them on the Council; but speaking as a member of the past Council he could say that nothing afforded them more gratification than to have their proceedings criticised or to have suggestions made for their consideration, and if those considerations were of weight they had always been accepted and thoroughly carried out. However, they had submitted to the members for two or three years, as they had that night, a list containing many more names than the number that constituted the Council itself, but he was sorry to say that that course had succeeded very badly indeed. In the first place, men of eminence and of position would not submit to a process of competition. When they were asked to allow their names to appear on the list to be submitted to the members for election they declined to be put into competition with brothers in their own profession. The result was that the best men would not consent to their names appearing among those of the candidates for selection. Again, there were many who had agreed to allow their names to appear on the house list, and who had been rejected in the process of competition; and he was sorry to say that there were two or three men whom he could name, but he thought it would be invidious to mention them, who had been very constant in their attendance at the Society's meetings, had evinced an absorbing interest in the Society's welfare, and who had taken an active part in the discussions, but who had, nevertheless, been rejected, although on account of the qualifications he had mentioned they were well worthy of the desire of the Council that they should be elected to the governing board. As a consequence these gentlemen had lost all interest in the Society, and had not come amongst them again, which was one of the most serious consequences of the process that they had adopted. Another very serious objection was this. Their Society had rapidly increased in numbers, the various fields in which electricity was being applied were rapidly extending, and it was quite evident that if the Council was to properly represent the interests of the Society it ought to mirror fairly and fully the wants and aspirations of each section of practical electricity. There was a very strong evidence of this desire in the correspondence that many of them might have noticed in the technical journals that week, notably in a letter signed "Telegraphist," wherein the writer pointed out that telegraphy, which was the origin of the Society, and whose members formed the largest section of it, but many of whom were scattered over the face of the earth, and therefore could not record their opinions, was consequently left to those few in London who were interested in the science, and who generally recorded their votes. Telegraphy was a very important branch of electrical science, and the Council had selected two of the most prominent and eminent members connected with the profession of telegraph-engineers, men who had held extremely high positions, and who would have been an honour to the Society, and forwarded its interests; but both those gentlemen had declined to appear on the Council list to be subjected to the competition to which he had alluded. There were other powerful reasons against the present system, with which he would not now trouble them; but the principal reason he would urge why they should return to their old practice was, that it was adopted by every other society except that which he had mentioned, viz., the Institution of Civil Engineers, and even there there was brought prominently before the Council last year the very motion he was now going to submit, that instead of presenting for selection a more numerous list of names than would form the Council, they should look upon the Council as the directors of a company who, if they neglected their duties, might be turned out at the end of the year. Therefore, he could not see why they should continue the practice, which had about it the very objectionable features that he had named, and he begged to propose that the Council revert to the old practice of submitting for election a complete list of the Council.

The PRESIDENT: By a complete list of the Council, you mean a list consisting of no more names than those who are to be elected?

Mr. PREECE: Exactly so.

Prof. FORBES seconded the motion, observing that Mr. Preece had adduced very forcible arguments indeed in favour of his contention, and he (the speaker) felt assured that everyone would appreciate them. The subject was brought before the Council at a recent meeting, and the cogency of Mr. Preece's views was then seen to be very strong. In consideration of a very general expression of opinion among the members, they had moved in the other direction a few years ago, and if the Council determined to revert to the ancient system the members ought to know what were the reasons that led many of the Council to think that the old plan was the best. He felt sure that the sense of the general body of the members would be favourable to Mr. Preece's proposal, and that they would see how undesirable it was that any unpleasant feeling should be aroused in consequence of the names of eminent men being put forward as councillors, and who might ultimately be rejected. He had great pleasure in seconding the motion.

Mr. H. C. DONOVAN considered that the old system of naming the exact number of candidates had created great dissatisfaction, because the majority of the members simply folded up the ballot papers and sent them back, without paying the least attention as to who were proposed for election. What was wanted was a number of names to select from, and if the Council could give some idea of the position of the gentlemen whom they nominated—their history, or something of that sort—it would be a distinct advantage (applause). There were numerous gentlemen on the Council whom he did not know—they might be telegraphists or electricians, but he did not know which. If a circular were issued, asking the members to recommend their candidates, then, he thought, the Council would be able to do better than they had done hitherto, though, as it was, they had done very well.

Mr. H. NEWMAN LAWRENCE said, as a humble member of the Associate class, he should like to say a word on this vexed question of the election of the Council, in which he was disposed rather to agree with the last speaker. Not the least of the difficulties to be overcome was the apathy of the members, who were rather given to criticism, and who generally shirked the responsibility of doing work themselves. No doubt there was great difficulty in both systems in getting at the exact wish of the great body of members, and although he was not prepared to oppose the motion of Mr. Preece in any way, he suggested whether it would not be possible, in reverting to the old system, to invite the members some time before the election to specially nominate certain persons whom they might think worthy of the honour of being selected by the Council as candidates for the votes of the Society. That might enable individual members to express their opinions in regard to any particular men or section of men, and perhaps to bring into deserved prominence men who were not likely to be otherwise noticed. He had heard from Mr. Preece with much regret that several of the most eminent members of the Society were so remarkably thin-skinned on the subject of selection (applause). He thought that anyone who was willing to accept a position in a society of that kind ought at least not to object to stand a contested election.

Dr. LANT CARPENTER said there was one point on which he wished a more precise statement for the information of some of the younger members. When Mr. Preece said that the Council should submit a complete list of names, he presumed that liberty would be allowed to members to erase any individual name and to substitute another. He raised this point because he thought it was extremely important.

Mr. PREECE stated that at the suggestion of the Secretary he proposed to word his resolution in this way, "That in future the list of members and associates proposed by the Council for election on the Council be limited in number to the number of vacancies to be filled." In answer to Dr. Lant Carpenter he would say that he did not propose to make the slightest change in the form or mode in which the election was made. At the present time everybody was at liberty to erase any name and substitute another, and that was a most necessary check to be maintained. Perhaps, if the suggestion of a circular being issued a month or two before the election asking the members to submit names were carried out the difficulty might be met, but that practice had not been in vogue in other societies. Personally, he should like to see the Council more varied than it was at present, as there was nothing so good for the Institute or for its members than that the latter should pass through the Council and see how the work of the Society was carried on, and the great zeal and regard for its interests which the members of the Council invariably exhibited. Mr. Laurence had said something about people being thin-skinned. Well, he thought it was human nature to be so. Until defeat was met with they all thought themselves to be cock of the walk, and when they were sent away with their tail between their legs they did not like it (laughter). However, whether they were thick-skinned or thin-skinned, if they could promote the interests of the Society without hurting the feelings of one of its members he thought they would have done a very good thing.

Mr. DONOVAN considered that the last suggestion would throw a very invidious task on the Council, as, owing to the apathy of the majority of members and associates, the Council's nominations would, in all cases, be elected, thus making the Council practically a self-elected body, which would, in his opinion, lead to much dissatisfaction. He thought some means might be adopted by which the voice of the interested should be heard and felt in the selection of members of Council.

Mr. W. T. GLOVER asked if this was a question which they ought to decide without notice. They all recollected the trouble which led to the change in the mode of nomination, and it appeared to him very much better that so important a departure should not be made without due notice being given (applause). Then those members who felt very strongly on the subject—and he knew there were a great many who did so—would have an opportunity of coming forward and recording their votes.

The PRESIDENT thought that some further discussion should take place. He did not know that there was any urgency, and if Mr. Glover was of that opinion he could move an amendment to that effect.

Mr. GLOVER said he would be glad to do so. He certainly thought that the members ought to be given a full opportunity of expressing their views on the subject before reverting to the old practice. He had great pleasure in moving that notice should be given of the motion which was before them.

Prof. FORBES suggested that Mr. Glover's object would be best attained, and the opinion of the whole body more fully elicited, if a circular

Digitized by Google

were sent round, so that everybody might see the discussion that had taken place. They would then be in a position to vote intelligently.

Mr. PREECE said that he quite agreed with Prof. Forbes in this regard. He had simply taken the opportunity of ventilating his views, and he deprecated very much their coming to a hasty decision. There was no need for immediate action, as they had eleven months in front of them in which to mature their plans.

Mr. GLOVER said he would withdraw his amendment if Mr. Preece would act upon his suggestion.

Mr. PREECE said he would make the addition to his proposition.

The SECRETARY suggested that the circular should only be sent to members in the United Kingdom. In this way he thought the general opinion of the members would be arrived at, whilst their decision on the question would be more quickly known than if they had to await the replies from Japan, New Zealand, and Kamschatka.

Prof. FORBES thought that would not be quite fair to the large class of telegraphists whose claims Mr. Preece had advocated.

Mr. PITMAN, as a member of the absentee class, demurred on behalf of his brother members in India to the Secretary's proposition.

The PRESIDENT hoped that Mr. Preece would cast his resolution into its final form (laughter).

Mr. MORDEY suggested that it was not quite desirable that Mr. Preece's statement of his views should be put forward alone for members to form an opinion. Mr. Preece very ably expressed one view, but if notice had been given it was probable that a strong expression of an opposite view might have been heard. He thought the circular to be issued should state bare facts, and leave the members to form their own opinion on the subject.

Mr. PREECE said that perhaps Mr. Mordey would give the other side. [Mr. Mordey made no response.] If they liked he would make another proposal, and in this form, that the Council issue a circular to the general members of the Society, asking them for their opinion on this question, and merely stating the facts, without putting it on the strong partisan grounds that he had done.

Mr. GLOVER: Then I have great pleasure in seconding that.

Prof. FORBES said his point would be quite met by what had happened. The reason why he did not wish the Council to decide the matter off-hand was that he felt that if the reasons were put before the members generally they would see that they were cogent reasons. He supposed some account of their proceedings would go forth to the world, and the general body of members would then know the motives that prompted Mr. Preece to take his present line of action.

The PRESIDENT then put the resolution as last amended, and it was unanimously agreed to.

The PRESIDENT having announced the result of the ballot as it appeared in last week's *Electrician*, the meeting adjourned until the 10th January, 1889.

[*A Correction.*—The name of Captain Wrottesley, who was elected as one of the Associate Members of Council, was printed in our last issue as Captain A. S. Wrottesley, R.N.; it should have been Captain A. E. Wrottesley, R.E.]

THE TRANSITION FROM METALLIC TO ELECTROLYTIC CONDUCTION.

The following interesting remarks form the concluding paragraphs of an important Paper by Mr. C. Barus on "Certain Generic Electrical Relations of the Alloys of Platinum" will be found in the December number of the American *Journal of Science*:—

"Taking the results collectively, they point to a limit below which, in the case of solid metals and at ordinary temperatures, neither electrical conductivity nor temperature-coefficient can be reduced; whence it appears that a lower limit of both conductivity and temperature-coefficient is among the conditions of metallic condition, not to say of metallic state.* These considerations are suggestive, and I shall therefore endeavour to make what I have in mind clearer. In the case of conduction in metals (solid or liquid) the effect of temperature is a decided decrease of conductivity, continuing apparently, as temperature increases, indefinitely.† In the case of conduction in non-metallic elements‡ or in electrolytes (solid or liquid), on the other hand, the effect of temperature is a decided increase of conductivity, which supposing the liquid state to be retained, continues as temperature increases. Hence conduction in metals is distinguished from conduction in electrolytes in this respect, that if the temperature coefficient in the one case (electrolytes) be regarded positive, its value in the other case (metals) must be negative. This leads me to inquire into the possible occurrence or the nature of a class of substances whose temperature-coefficient is zero; a class of substances, in other words, in which the metallic and the electrolytic modes of electric conduction may be supposed to converge.*

The point which I have in view, viz., the possibility of a continuous transition from metallic to electrolytic conductivity gains much in reasonableness by associating with good metallic conductivity the correlative property of optic opacity. Relations between electricity and light have been investigated, and many experimental facts are known. Maxwell's electro-magnectic theory of light furnishes a theoretical basis for the fact that, true conductors are exceedingly opaque. The resistance of solid metals, however intensely they may be heated, is found to increase so long as temperature increases. Nevertheless the careful experiments which Govi† made to interpret an erroneous result of Secchi‡ prove that solid metals even in extreme states of white heat remain opaque. In the case of liquid metals at extreme white heat the case is not so definitely established; and the question relative to the ultimate transparency of liquid metals at very high temperatures is an open one.§ It is in the direction of ultimate transparency that the observed continuous increase of resistance with temperature seems definitely to point.

It is reasonable to infer that the transition from opaque to transparent‖ will take place in the region of the critical temperature. At least such transition must ultimately occur; and I am led to conjecture that the said transition from opaque to transparent will be accompanied by a change of the values of the electrical temperature-coefficient, passing from the negative value which holds for the liquid metal, to the positive value which will probably hold for the gaseous metal, continuously through zero. The fact that conduction in gases is of an electrolytic nature was proved by Varley,¶ who showed that after the polarisation of the electrodes is overcome, gases obey Ohm's law. The electric *strength* of air is known to diminish rapidly as temperature is increased. Working with hot gases carefully insulated and protected from flames, Maxwell** was unable to obtain conduction either in hot gases like air or in hot metallic vapour like Hg or Na. At higher temperatures (red heat) the researches of Blondlot,†† confirming the observations of E. Becquerel,‡‡ prove that hot gases are conductors, and that at temperatures sufficiently high $\frac{1}{1000}$ volt is enough to set up a current. Hence in their thermal relations also gases ultimately partake of the nature of an electrolyte, and the occurrence zero value of the temperature coefficient may be reasonably associated with the critical temperature of the metallic liquid, passing continuously from the liquid into the gaseous state.

* Recent researches of *v.* Ettingshausen and Nernst and of C. L. Weber (Wied. *Ann.*, XXXIV., p. 582, 1888), show that the resistance temperature-coefficient of bismuth is often negative between 0° and 100°. Edward Weston has made alloys of copper, ferro-manganese and nickel of which this temperature-coefficient is nearly zero or even negative (*Science*, XII., p. 56, 1888). These exceptions, the underlying cause of which is probably secondary, and to be referred to structural or crystalline modification, emphasise the vast amount of evidence in favour of the normal behaviour given in the text. I may add, for instance, that the temperature-coefficient of glasshard steel between 0° and 100° would be nearly zero, because of annealing.

† Following Benoit (*C. R.*, LXXVI., p. 342, 1873) the electrical resistance of all metals increases with temperature at an accelerated rate, except in the case of platinum and palladium, where the rate of increase is retarded. Benoit observes at temperatures limited by the boiling point of zinc.

‡ Matthiessen (Pogg. *Ann.*, CIII., p. 428, 1858), W. Siemens (Wied. *Ann.* X., p. 560, 1880), and others (Bergmann, Kemlein, Muraoka) find this to hold for modifications of carbon. Similar increases of conductivity are usually observed in the case of selenium and tellurium (Hittorf. W. Siemens, Matthiessen, and many others); but the relations here are complicated. Quite recently Duter (*C. R.*, March 19th, 1888) has shown that sulphur conducts at its boiling point. It is this investigation which I have specially in mind in the text.

* Something of the kind may perhaps occur in the case of some natural sulphides, but it is not open for systematic study, and its nature is obscure.

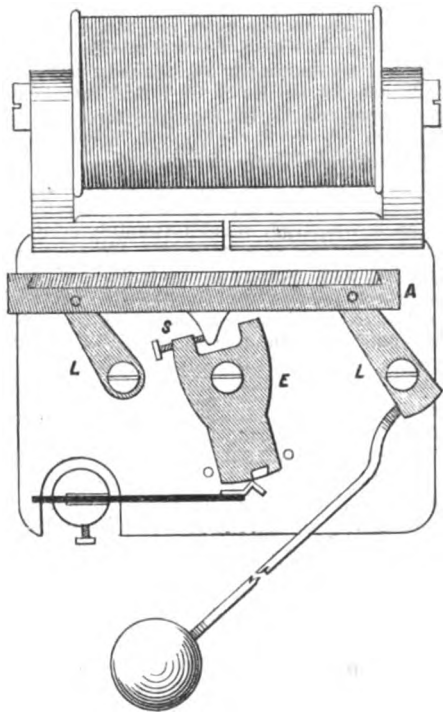
SNELGROVE'S ELECTRIC BELL.

Messrs. W. and T. Avery are introducing an electric bell designed by Mr. Snelgrove, which differs in several important details from the ordinary designs. As will be seen from the figure, the poles of the magnet are bent round so as to form an almost closed magnetic circuit; while the armature A, when vertically attracted by the magnet, is constrained by the links L L to move in a horizontal direction, striking as it travels against the upper jaw of the oscillating switch E and breaking the circuit, this horizontal movement being also utilised to strike the bell. There are several advantages gained by this arrangement. Owing to the almost closed magnetic circuit, and the approximately parallel travel of the armature (which even at its most distant point is comparatively close to the magnet), a weaker current can be used than is usually possible. Additional power is also obtained owing to the fact that the electric circuit is not broken until the moment before the hammer strikes the bell, thus producing a more powerful effect, with equal battery power, than is obtained from the ordinary "trembler." Snelgrove's bell can be used either as a continuously ringing bell,



A, Armature. LL, Links. E, Oscillating Switch. S, Adjusting screw for varying length and duration of stroke. D, Insulated contact post, with contact spring tipped with platinum, bearing against E.

or by simply connecting up to the third terminal screw it will work as a single-stroke bell; one bell can, therefore, if desired, serve two distinct rooms, one ringing single and the other continuous strokes.

BARCELONA INTERNATIONAL EXHIBITION.

The following awards have been made in the Electrical Section of the Barcelona International Exhibition:—

GOLD MEDAL.

Anglo-American Brush Company (London)	Magic fountain.
Bonnet, Enrique (Spain)	Electro-magnetic receptors.
Belleville, J., and Co. (St. Denis, France)	Steam boilers for electric light engines.
Babcock and Co. (New York)	Tubular boilers for electric light engines.
Bertran Rubio (Barcelona)	Electro-medical apparatus.
Ganz and Co. (Buda Pest, Hungary)	Dynamos.
Mildé Sons and Co. (Paris)	Micro-telephonic apparatus.
India Rubber and Gutta Percha Company Telegraph Works (Persan Beaumont, France)	Cables for electric light and other purposes.
Société Générale de Telephones (Paris)	Micro-telephonic apparatus.
Saxby and Farmer (London)	Electric apparatus connected with the block system signalling for railways.
Sociedad Española de Electricidad (Barcelona)	Electric light apparatus.
Fuisseaux, De (Bandow, Belgium)	Porcelain insulators for electric purposes.
Weyher and Richmond (Paris)	Steam engines for electric lighting.

SILVER MEDAL.

Cabeza de Vaca, Francisco (Spain)	A nemascope.
Conradt and Co. (Nuremberg)	Carbons for electric light and other purposes.
Corominas, Ramon (Barcelona)	Electro-medical apparatus.
Charlesworth, S., & Co. (Oldham)	Dynamo.
Galante, José (Spain)	Manual on electricity.
Mayer and Meltzer (London)	Electro-medical apparatus.
Orduña, Carlos (Spain)	Duplex system.
Perez Blanca, Francisco (Spain)	Treatise and manual of telegraphy.
Perez Santano, Miguel (Spain)	Duplex system.
Planas Flaquer and Co. (Spain)	Dynamos.
Gallé, Richard (Berlin)	Electro-medical apparatus.
Suárez, Saavedra (Barcelona)	Treatise on telegraphy duplex system.
Tomasino, Pablo (Barcelona)	Lightning protectors.

BRONZE MEDAL.

Garcia Montalban, Abelardo (Spain)	Double manipulator, &c., for stations.
Hediger, Ruiz (Mahon, Spain)	Electric batteries.
Neville and Co. (Liverpool)	Arc lamps.
Chimkewitch, Peter (St. Petersburg)	Modifications in telephones.
Nicholson, Mambray Steel Works (Sheffield)	Dynamo and lamps.
Piedras, Victor (Spain)	Electric apparatus for intermediate stations.
Spagnoletti and Sons	Electric fire alarms.
Stöker and Co. (Leipzig)	Telephonic apparatus.
Schukert, S. (Nuremberg)	Dynamo and electric lamps.
Schilling, Ermanno (Barcelona)	Electrometer.
Vigil, Primitivo (Spain)	Apparatus for testing strain, torsion, &c., of wire and metals applied to telegraph material.
Vilafranca, Pablo (Barcelona)	Copper and bronze wire for telegraphic and telephonic uses.

HONOURABLE MENTION.

Actien Gesellschaft, Seel and Co. (Berlin)	Electric lamps.
Bons, José (Barcelona)	Points for lightning protectors.
Fernandez Arias, Gregorio (Spain)	Electric apparatus applied to telegraphy.
Ibañez, Alonso Joaquin (Madrid)	Electric commutator.
Loiseau and Pierrard (Paris)	Electric apparatus.
Rey and Villanueva (Spain)	Manipulator for intermediate telegraph stations.
Ruiz and Verd, Pablo (Mahon)	Hydro-electric battery.
Rodriquez, Manuel (Spain)	Points for lightning protectors.
Spiecker and Co. (Cologne)	Dynamo and automatic regulator.
Villahermosa (Spain)	Electric apparatus for intermediate telegraph stations.

A DIPLOMA OF HONOUR has also been given to the Spanish Administration of Posts and Telegraphs for their exhibit of past and present telegraphic apparatus and material. Only the exhibits of Governments are entitled to Diplomas in this Exhibition.

LEGAL INTELLIGENCE.

Edison and Swan Electric Light Company v. Holland and Others.

MONDAY, DECEMBER 10.

Mr. FINLAY resumed the argument by commenting on a judgment in a previous action delivered by Lords Justices Fry and Bowen. The learned counsel read an extract from the judgment of Lords Justices Fry and Bowen in the Woodhouse and Rawson case, as follows:—"As far as we have learnt there are only two specimens of the earlier form of the instrument, and in both these a rod and not a filament of carbon has been adopted. Mr. Edison used it for a definite purpose, and by a diminution of a sectional area made a subsidiary law which carried out the end in view, and so converted failure into success." The learned counsel remarked that the evidence was very different indeed in the present case from what the evidence would have proved in the former case.

LORD JUSTICE BOWEN: In the former case it was distinctly admitted by the defendants that the patent was intelligible for any ordinary workmen to make a lamp that would burn. It was not an assumption; it was the result of evidence so strong as to be admitted by the defendants' counsel as incontrovertible.

Mr. FINLAY: But what I said just now was directed to the principle. In the former case the observation I made was in this passage:—"Mr. Edison used the filament for a definite purpose, and made a subsidiary law subserve the end he had in view. Your lordship now knows that so far as the success of the lamp goes it succeeded perfectly well with a rod, as in F I B 1.

Sir RICHARD WEBSTER: That is your statement.

Mr. FINLAY went on to say: The majority of the Court shows that they laid great stress in that case upon two things, both of which were presented in a very different aspect by the evidence in the present case. The first is that they regard Edison as the discoverer of the idea that by taking a small sectional area in the carbon conductor a physical law may

Digitized by Google

be made to yield results valuable in the way of incandescent lighting, as regards not merely the combination for the purpose of multiple arc lighting, but as regards the individual lamp itself. In the second place they assume that there was a great outburst of incandescent lighting following upon Edison's lamp of 1879. I do not desire to repeat what was said by Sir Horace Davey on this point, but there is a mass of evidence now before the Court, which was not before the Court in the previous case at all, as to the state of knowledge among those concerned in these matters before 1879, and I think it is now established that it was common knowledge that the reduction of the sectional area of the carbon conductor would be of great use for the purpose of incandescent lighting. It was not, of course, common knowledge that it would be useful so far as the individual lamp is concerned, because the reduction of the size of the carbon conductor is rather a disadvantage, because it reduces the light of the lamp; but it was perfectly well known to every electrician, and it was proved both by the witnesses for the plaintiff and defendant that this reduction of the sectional area of the carbon conductor as a desideratum was perfectly well known, so that the first point which the Court assumed on the previous occasion is, I submit, entirely gone. On the second head I would point out that there is an assumption embodied in one passage of their lordships' judgment, which I shall read—"The importance of this combination can hardly be doubted, for it has had this result afterwards. Before November, 1879, two or three experimental lamps were all that had been produced; after that date such lamps had been produced by tens of thousands, and constituted a most important element in other methods of electric lighting." Though not directly stated, the assumption of that statement is that shortly after November, 1879, there took place in consequence of this invention of Edison an outburst of activity. I venture to dispute that, and I shall proceed to show that there is not even a coincidence in the so-called outburst of electric lighting, as suggested by Mr. Aston. In order to do that I shall draw attention to the stages of this invention in the way of electric lamps in 1879, 1880, 1881, and 1882. The patent now in question was the 10th November, 1879. On the 15th December, 1879, Mr. Edson took out the cardboard patent. Then, on the 2nd January, 1880, Mr. Swan took out his patent for running on the pumps. Now, let me point out the result of the evidence; it was perfectly well known that in multiple lighting, with the conductor of a small sectional area, there were two difficulties; the first was how to make a carbon conductor, and anyone who could discover a good process for making such carbon conductor would be entitled to take out a patent for it. The other point was the difficulty of securing a perfect vacuum, and that arose in this way—although the use of the Sprengel pump had enabled them to obtain a good vacuum in the first instance, yet, owing to the gases which were occluded in the conductor and in the platinum wires when the lamp afterwards came to be run, those occluded gases were expelled, and you no longer had your perfect vacuum. With both these difficulties Swan deals in two patents taken out in the same month. The first refers to the question of occluded gases.

LORD JUSTICE BOWEN: It is material to know that this invention was made by this time, but I do not see how putting a statement of Mr. Swan's in that he did make it proves it.

LORD JUSTICE LINDLEY: Your object is to prove that the outburst was due to other things.

Mr. FINLAY: In the first instance I wish to prove that the outburst was not until long afterwards, and, in the second place, I am going to show to what it was really due. For my purpose it does not matter whether Mr. Swan is the true inventor of running with pumps or not; but my purpose is to show the real history as to the activity in electric lighting.

LORD JUSTICE LINDLEY: The fact was that there was another improvement.

Mr. FINLAY: Yes.

LORD JUSTICE BOWEN: This patent of Swan's proves no doubt, that from this time it was known after, but it does not prove that it was known before.

Mr. FINLAY: My point is this, that it was about this time that that process came into notice, and I think I can show that. If you turn to Mr. Swan's cross-examination he says the word "filament" was not used in 1879. Then Mr. Swan was asked if he were troubled with smoke in his lamps, and he replied one of the difficulties was the blackening.

LORD JUSTICE COTTON: You are passing by what may be material—the words "filament was not used at that time."

Mr. FINLAY: His answer showing that the words "filament was not used at that time" was a most material answer, which was discussed by Sir Horace Davey as to how far the judgments in the previous case gave any definition of the word "filament" which is binding on your lordships here.

LORD JUSTICE BOWEN: The difference between the two judgments on this point seems to me to come to this, that the majority of the Court take the view that Swan's rod is not a filament, and Lord Justice Cotton seemed to think that if you took the filament in the widest sense Swan's rod might have been a filament; but then he thinks that the word is used not in the wider sense but in the more specific sense, and that by implication it was to be formed before being carbonised. In that case, Swan's rod would not be a filament, as it was not carbonised until after it was made.

Mr. FINLAY: Exactly.

LORD JUSTICE BOWEN: That is what the two views came to; but then we must consider how far we are bound by the judgment of the majority; the judgment of the majority being that the filament being taken on the larger view, Swan's rod was not a filament.

Mr. FINLAY: I submit there is no very clear decision of the Court to that effect, and, if so, it would be a mere matter of fact, which in no way trammels your lordships in dealing with the present appeal.

LORD JUSTICE BOWEN: That may be. We did take the view that it may be a matter of law.

Mr. FINLAY: How can it be a matter of law?

LORD JUSTICE BOWEN: That is a question. How could there be in the "Law Reports" a head note to this effect—"Whereas $\frac{1}{25}$th of an inch in diameter is not a filament, but the $\frac{1}{1000}$th is?" That must be a matter of fact to be determined in every case according to the evidence by the appropriate tribunal.

LORD JUSTICE BOWEN: If it was a fact, all that I say is if that I drew a wrong inference on that fact, I should change my mind.

Mr. FINLAY: Of course where the evidence is different one must necessarily come to different conclusions where the same question arises. All that was decided in the previous case was on the evidence then before the Court. Let us take the illustration of Lord Justice Cotton. If the Court laid down that in a particular Act "horse" included "mare," no doubt so far as that general principle goes the Court would be bound afterwards, but in every case it would be for the jury to decide whether it was a horse or a mare upon the evidence, and if the Court had come to the conclusion that it was a mare it would be at liberty to say that it was a horse.

LORD JUSTICE LINDLEY: Or neither.

Mr. FINLAY: Or neither or both. Now I have been a little turned aside from a point of very great importance, as to the running on the pumps. Mr. Swan was asked if he was troubled with something in his lamps, and he replied, "Yes, one of the difficulties we had to compete with was the blackening of the bulb. The only assistance I received from Mr. Proctor in connection with the blackening of the globes was the investigation of the nature of the deposit of the broken lamp shown at the Chemical Society. I took up a patent in January upon the running of the pumps, and I claim a patent for running on the pumps for the purpose of getting rid of the occluded gases. *Q.* Did you not intend to show that you could produce an incandescent-lamp horse-shoe cardboard conductor?—*A.* An improvement on running on the pumps. I did look upon the improvement of running on the pumps as the greatest barrier in making a satisfactory incandescent lamp, and afterwards I found other difficulties, and I think I was a little premature in saying that I had conquered all the difficulties." I submit that that evidence establishes that during the year 1879 electricians had been bothered (and there is no evidence to the contrary as far as I know) with the occluded gases blackening the lamp, and that Mr. Swan considered that he had discovered the mode of dealing with that, and that he embodied that discovery in his patent on the 2nd January, 1880. This patent describes the process of running on the pumps. It keeps the pump in action while the current passes through the lamp. Then comes Swan's patent of 20th January, 1880, for overcoming the difficulty as regards the manufacture of those carbon filaments. I have submitted that the principle was perfectly well known; that the practical difficulties were two—first, the occluded gases blackening the globe, and secondly, how to manufacture the carbon conductor. The first of these difficulties Swan dealt with on the 2nd January, 1880, and with the second on the 20th January, 1880. On the trial before Mr. Justice Cave, my friends endeavoured to show that this patent of November, 1879, had put Swan on the right track, and that in some way or other he was indebted to it. But that patent was not published until May, 1880, and if your lordships will look at the drawings you will see that Swan had nothing to gain from the patent of Edison with regard to this question of carbon filament.

LORD JUSTICE BOWEN: We recognise the importance of your argument, but we only doubt whether you are proving it in the right way.

Mr. FINLAY: Those two patents of Swan could have had nothing to do with the patent of 1879.

LORD JUSTICE BOWEN: Still, after the running on the pumps, there were two defects. The first was the cracking or leaking of the glass bulb, which he remedied by this platinum. The other one was the practical difficulty of the inner arch of the cardboard, which he remedied by taking a strip, cut straight, instead of in the form of a horseshoe.

Mr. FINLAY: I wish to follow out the history of this matter Edison's patent was December, 1879, his cardboard patent, and Swan's patent for cardboard paper was next. Then in the early part of 1880 Mr. Johnson gave Dr. Fleming six Edison lamps. Then Swan, when being cross-examined by me, said: "*Q.* With regard to those lamps brought over by Mr. Johnson, when was it?—*A.* In the beginning of February, 1880. *Q.* You are familiar with the patent?—*A.* I know the specification generally; it is for making burners out of cardboard." We say that these lamps were made under the cardboard patent of 1879; but your lordships see what they are intending to do. They were running in what was called an installation in February, 1880, and the suggestion was that this was under the patent of 1879. If that were so they had the means of proving it beyond all doubt. They could have proved it by Edison and Johnson, and in many ways if the fact were so. They did not attempt to do it, because the lamps were made under the specification of December, 1879, and we say that we have given by the cross-examination of that gentleman *prima facie* evidence that this was an attempt to show that his lamps were made under the patent of November, 1879, whereas the lamps were made under a patent taken out a month afterwards.

LORD JUSTICE BOWEN: Do you suggest that it is made under the cardboard patent?

Mr. FINLAY: I suggest that they were made together under the cardboard patent. The importance of this point is, when we challenged that any lamp had ever existed under the patent of 1879, except for the purpose of litigation, if my friends could have proved it they certainly would.

LORD JUSTICE COTTON: If your object is to remove the impression produced in the former case that the great start in electric lighting was in consequence of the patent of 1879, I may tell you that I am not impressed by that argument one way or the other. If that is a good patent, although a great start was not made in consequence of it, yet it would be within the patent.

Mr. FINLAY: Really, then, the November, 1879, patent was veiled in obscurity until it was discovered as a patent to run this claim for a monopoly, but for all practical purposes it was brought out into the light

Digitized by Google

of day for the purpose of an action against Mr. Swan, and Mr. Swan swore an affidavit that the patent was bad.

LORD JUSTICE BOWEN: Does not that resolve itself into these two points, first you say that the idea of a filament in a larger sense was not obtainable?

Mr. FINLAY: Yes.

LORD JUSTICE BOWEN: And, secondly, that the process given for the manufacture was not workable?

Mr. FINLAY: Yes.

LORD JUSTICE BOWEN: It is only the same argument in a different shape.

Mr. FINLAY: It is illustrating by the evidence of its history what we say is the worth of our argument. His patent of 1879 was brought to bear in 1879, and Mr. Swan swore that the patent was bad, but the two parties formed themselves into a company in which Mr. Swan took the greater part of the shares.

Mr. MOULTON: No.

Mr. FINLAY: That is proved; and the two having combined their forces, they proceeded to attack all other manufactures in detail. But this patent of February, 1879, never had any value except for the purpose of litigation.

LORD JUSTICE LINDLEY: It was never litigated between Edison and Swan.

Mr. FINLAY: There was no decision of the Court at all, but the fact that in the compromise Swan got rather the larger share, shows how that went.

LORD JUSTICE LINDLEY: That we have nothing to do with.

Mr. FINLAY: What I desire to do in the way of tracing the history of the case is this:—On the 16th September, 1880, Mr. Edison took out his bamboo patent. In the late autumn of 1880 Mr. Stearn's house was lit with Swan lamps. On the 24th November, 1880, the Swan lamps were exhibited at the Institute of Civil Engineers, as proved by Prof. Perry. In the same month, in November, 1880, Mr. Swan took out his patent for the use of parchmentised thread; and at the end of 1880 Mr. Swan, as he states, made a considerable number of lamps. With Swan's lamps Mr. Crookes's house was lit up in December, 1880—that is proved by Mr. Crookes and Prof. Frankland. In February, 1881, Mr. Bernstein visited the Edison works in America, at Menlo Park, and the lamps that he found Edison making were the bamboo lamps like E. F. 1. Every lamp that Edison ever sold we say was made under this bamboo patent. In July, 1881, there was an exhibition of Swan lamps at King's College, and that is proved by Mr. Crookes. In August, 1881, there was an exhibition at the British Association of Swan lamps, at the York Meeting, and that was proved by Prof. Thompson and Prof. Perry. In September, 1881, at the Paris Exhibition, there was a display of Swan lamps and the Edison lamps, and that is proved by Mr. Crookes and Prof. Thompson. There was at the Paris Exhibition a great many thousand of Swan lamps, and Prof. Frankland says that there were not so many Edison lamps there. The lamps exhibited at Paris, in September, 1881, were lamps made under the bamboo patent. I will not trouble your lordships by going through the eleven points of difference which were proved by Prof. Thompson, but September 1881, with the exception of that small exhibition of half-a-dozen or so in February 1880, was the first time that the Edison lamp was exhibited in Europe. In 1881 the Savoy Theatre is lit up with the Swan lamps, and that is proved by Prof. Perry. September, 1881, was the first time that Mr. Crookes, Mr. Frankland, Prof. Thompson, Prof. Perry and Mr. Swinburne ever saw an Edison lamp. All these are gentlemen who are certain to have known what was going on in the matter of electric lighting, in which they took great interest. They were skilled, and they saw that it was the bamboo lamp. Then there was an exhibition in the early summer of 1882 at the Crystal Palace. I defy my friends to say that this patent of November, 1879, had anything to do with the bringing into life of that industry in incandescent electric lamps. I defy my friends to point out in the evidence any foundation for that statement which was made in the previous case and which really seemed to a considerable extent to have influenced the minds of some of the Court. I am not at all sure that my friends have not benefited in this litigation by a sort of association in the minds of many between the Edison lamp and the great scare with regard to the value of gas shares which took place in consequence of the supposed invention of Mr. Edison. That took place in 1878, in consequence of Edison's advertisement of the platinum lamp that he had invented.

Mr. MOULTON: It is not fair for my friend to state that.

Mr. FINLAY: I do not see that my friend has any reason for objecting.

LORD JUSTICE COTTON: I do not know that that would influence the Judges of the Court of Appeal—and you are before them now—whatever it might do with any other tribunal.

LORD JUSTICE LINDLEY: Do not go into gas shares.

Mr. FINLAY then referred to the evidence of Mr. Proctor to show the experiments made by Mr. Swan in 1879. The lamps then made were seen by many people at Mr. Swan's works, and they were lamps which burnt fairly well. They were all vacuum lamps, with carbon conductors and platinum leading wires; the carbons would vary in thickness, but thinness was aimed at. He thought they could rely upon the dates given by Mr. Proctor, testing his evidence by the light of Mr. Swan's cross-examination. He submitted that whatever doubt or obscurity there might be with regard to some of the lamps made by Mr. Swan, it was perfectly clear, from his admissions in cross-examination, that before November, 1879, he was making lamps with the little horse-shoe hairpin Carré carbons. He did not, however, know that any cards were used before November, 1879. He wished to call attention to the very odd way in which Mr. Swan gave evidence with regard to the paper; he did not impute the slightest want of good faith, but it was clear that Mr. Swan was mistaken. On Dec. 29, 1879, Mr. Swan wrote to *Nature*, stating that fifteen years before he had used charred paper and cardboard for the construction of incandescent lamps, and that he had used it in the shape of a horseshoe precisely as Mr. Edison did, but that he did not succeed in obtaining the durability he was in search of. He went on to say: "Within the last six months I have, I believe, completely conquered the difficulty which led to previous failure, and I am now able to produce a perfectly durable electric lamp by means of incandescent carbon." That would take one back to the middle of 1879.

In reply to LORD JUSTICE COTTON,

Mr. FINLAY said Mr. Swan had admitted this to be correct, and had suggested that the mode of overcoming the difficulty was the running on the pumps. On the 20th January, 1880, Mr. Swan took out his patent for making the horseshoe conductors, the filaments being shown in a very filamentous form in the drawings annexed to the patent. Mr. Swan having taken out that patent in January, 1880, and having three weeks before written to *Nature*, stating that within the last six months he had overcome the difficulties with regard to the use of horseshoe filaments with charred paper, Mr. Finlay suggested that he must have been mistaken when he said he had not been experimenting with cardboard or working with cardboard or charred paper for the purpose of making these burners since ten or fifteen years before. Mr. Swan did distinctly swear that he never made a lamp with a carbon conductor of thread until the year 1880, and not having been shaken on cross-examination with regard to it, he was entitled to the benefit of having clearly contradicted Mr. Proctor on that point. Mr. Finlay did not, however, think it was suggested that Mr. Swan was in any way led to use thread by the patent of November, 1879. The learned counsel then read the evidence of Mr. Heaviside for the purpose of showing that Mr. Swan at that time owed nothing to Edison's patent of November, 1879. This evidence, coupled with Mr. Swan's admissions, proved that Mr. Swan working in his own lines independently of Edison, before Edison, and after Edison, without knowledge of the patent of November, 1879, was getting a lamp of the kind that was put forward as having made this revolution in electric lighting.

LORD JUSTICE COTTON: The impression upon my mind is that both Swan and Edison were working at the same time and for the same point, but that Edison got out his patent first. Then the question is whether Edison did get out a good patent.

Mr. FINLAY said that relieved him from going any further into detail. He then referred the Court to the evidence given by Mr. Mayfield, Mr. Ridley, and others, who were called to prove that Mr. Swan, in conjunction with Mr. Stearn, was in 1879 making lamps with a carbon filament. He did not think what had happened at Mr. Stearn's would have prevented them from afterwards taking out a patent for what they had done; but the importance of this evidence was that it bore out his statement that Mr. Swan and other electricians working in this country really owed nothing to Mr. Edison's patent of November, 1879. The other side had protested very much against Mr. Justice Kay's application of the doctrine of commercial utility to their lamps, and said that those lamps ought to be judged by some other standard; but if that looser rule availed the other side, it also availed him as regarded F J B 1, which he said was an anticipation. In conclusion, he claimed that the defendants had broken down the specification on the questions of the sufficiency of description and of its utility, upon the three points of carbonisation, tar putty, and pyro-insulation.

At the conclusion of Mr. Finlay's speech the case was again adjourned.

(To be continued.)

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *December 8th*, 1888.

The announcement has been made during the past week of another absorption by the Western Union Telegraph Company. The lines taken over in this instance are those with which the Atchison, Topeka and Santa Fé Railroad have carried on a commercial business for some time past. There are about 2,000 miles of line involved in the purchase, it is said, together with about 1,500 miles in Texas and the Indian territory. In some quarters surprise is expressed that the Western Union Company should find any lines to absorb at this late day, but the fact is there are still a large number of small companies doing an independent business. Although the individual totals are insignificant, probably the aggregate would not be a small one. In the case of the railroad which is mentioned the commercial telegraph service was very much in the nature of what is known here as a "side show," and there need be no great surprise that the transfer should be made to the Western Union Company. One of the immediate and direct benefits to the public has been a reduction of 25 per cent. in the rates, and the opinion is that the telegraph service at all the points reached will be greatly improved.

While the Western Union Telegraph Company thus maintains its old policy of acquisition, and ever and anon enters into possession of some new territory, exemplifying territorial growth very much in the same way that the British Empire does, on the principle that the only way to protect the present frontier is to establish another one a little beyond it, the

American Bell Telephone Company very seldom has an opportunity to buy out a rival or competitor. Its opponents long ago said that it owned the earth and wanted the water too. This was, after all, a jealous acknowledgment of the fact that the Bell patents covered the whole practical field of telephony, and have been rigidly enforced in every instance, so that no competitor has ever been allowed to make any great headway. Since the day when the Western Union Company went out of the business and agreed to take 20 per cent. of the gross earnings of the American Bell Telephone Company as a reward for sitting still and doing nothing, almost all the opposition companies of which we have heard so much have been largely on paper. There have been a number of Baxter, Wallace, Clay, Pan-electric, and other instruments in use from time to time, but the aggregate was always very minute, and the effect of the use of these infringing instruments has in each case been purely local. And these facts give more prominence than it would otherwise receive to the fact that the American Bell Telephone Company has just purchased the entire plant of the Superior Telephone Company of Wisconsin for $35,000. Under some circumstances this might mean a great deal, but the simple explanation is that the Superior Company has a plant of poles, line, &c., which had a market value, and which it was cheaper to buy than to replace. So far from feeling any weakness in the matter, the American Bell Telephone Company has been rendered invincible in that quarter by the perpetual injunction which has just been issued by the United States Court at Chicago restraining the infringing Inter-State Telephone Company from any further operation whatsoever.

One of our papers here has lately devoted itself to a systematic attack upon the work of the Board of Electrical Control. One of its reporters states this week that he watched the laying of the iron pipes in subways in Twenty-fourth and Twenty-fifth streets a few days ago, and that the iron tubes which are used were in actual contact when the asphalte cement was poured over them, although the very object of the cement is to keep these pipes apart. He further asserts that when the manholes of the conduit on Sixth-avenue were opened for the purpose of making repairs they were frequently found full of water, and had to be pumped out before the workmen could get down to the ducts through which the cables ran. So common has it become to find the manholes full of water, he says, that a suction pump is now an essential part of the kit carried by the Construction Company with their waggon. Hence, with water and gas, and iron tubes which lie together instead of widely apart, the conduits are allowed to be in very bad shape, and this is instanced as a good reason why the local lighting companies should not be driven into them. The reporter winds up by saying, "It is not at all remarkable that the various companies operating the lights should decline to place their conductors in conduits which both experiment and common sense have shown will not meet their requirements. Those who have tried them will not do so again, and those who have not will not." While these newspaper articles are not to be accepted as the best evidence in dealing with so complicated a question as that of putting the wires underground, their appearance is an indication of the bitterness of the struggle which is now going on. In our neighbouring city of Brooklyn matters between the Subway Commissioners and the various electric companies appear to be in a more harmonious state. This arises partly from the fact that the Commissioners have not been very urgent in their demands for the burial of the wires, and because they have given the companies a great deal of latitude as to the systems to be laid down and experimented with. An important piece of work has just been finished by the New York and Brooklyn Telephone Company, which has laid a number of conductors underground, using the Brooks oil system, with which, probably, your readers are familiar, the main idea being to saturate the textile cover of the cables with a mixture of resin and resin oil, and then to draw the cables into the wrought-iron pipes, into which, after the cables have been pulled in and spliced, a quantity of the same mixture is poured until no more can be introduced. Good results have been obtained with this system in telephone work in New York and Philadelphia, and it is believed that success will also be enjoyed in Brooklyn.

Mr. W. McGrath, the superintendent of the local Brush Company, is reported to have said to one of the New York Subway Commissioners that the growth of electric lighting in this city during the present year has been no less than 200 per cent. This may seem an exaggeration, but to those of us who witness the tremendous growth that goes on it does not seem very much out of the way. Not only is there a steady and large increase in the number of street lights in the old districts, but in the suburbs new circuits are put up every day, and this is supplemented by a brisk demand for lights in front of stores, hotels, theatres, and such places. But the chief growth occurs in connection with incandescent lighting. A large number of these lights are supplied from the street circuits, but it is becoming the practice for every large new building to have its own plant, and in order to render some older buildings more attractive, incandescent plants are being put in. At the present time the increase in the number of isolated plants is really very remarkable, but it remains to be seen whether the starting up of the large new central stations will not put a check upon that part of the work. Up town, for example, where the new Edison stations are about ready to go into operation, it may be taken for granted that some of the proprietors of the places where isolated plants are being installed will find it more convenient to take their current from the street mains, though, as I have said, just how far this will be done is uncertain. These places—hotels, theatres, &c.—with a large number of lights, ranging from 500 to 2,000, prove good customers for the central stations, and tempting inducement would be offered them.

It is reported from Chicago that Prof. Elisha Gray is about putting the finishing touches to his telautograph system, which was recently described in the technical papers. It is claimed that the reproduction made by the instrument is just up to the point of not being the original. The difference is enough to prevent long-distance forgeries, and at the same time the copy at the other end is so nearly like that which is written at the sending end that, for all ordinary purposes, it is the same handwriting. It is intended, of course, to put the new system in competition with the telephone, but perhaps there will be more limitations to its employment than are now supposed. If it be anything like what it is said to be, there will be nothing to prevent our special artists at the seat of war, or any other seat, from sending in an illustrated account of what is going on. In this way the reader of the daily paper will not be dependent upon his imagination for the description given in the letter, but he will be able to gather from the sketches just how things happened. This will be quite a development of journalism; but it will not hold a candle to the journalistic enterprise with which Mr. Edison is credited, namely, the issuance of a talking daily newspaper. The idea of this appears to be to charge the record cylinder with a condensation of the news of the day, so that each subscriber can listen to the instrument while at breakfast, and will not be under the painful necessity of borrowing first the sugar bowl, then the milk jug, the coffee pot, or the toast rack to prop up his paper with. If a new opera has been produced the night before, he can listen to an able but concise criticism of it, and enjoy with his family the sensation of having repeated the choicest passages of the music just as they were rendered at the theatre by the *prima donna* or the "star" tenor. These various suggestions and promises leave one very much in doubt as to what the newspaper of the future will be like.

Two very important circulars have been issued by the Westinghouse Electric Company, under the date of December 1st, with regard to the contracts and arrangements heretofore existing between them and the Thomson-Houston Company. It is announced that the limited license accorded to the Thomson Houston Company to make alternating apparatus under the Westinghouse patents has been terminated, and that so far as those patents have any scope or validity, the manufacture of such apparatus by anybody but the Westinghouse people themselves will be an infringement. It is stated, moreover, that the Westinghouse patents cover not only what is known as the ordinary alternating system, but the fundamental principle of what is called the Thomson compensating system,

Digitized by Google

which has lately been introduced with success by the Thomson-Houston Company. The circular takes cognisance of the fact that an arrangement now exists between the Thomson-Houston and the Fort Wayne Jenney Companies with regard to the use of the alternating system, and that the latter company is controlled by the former. The second circular referred to states that the Westinghouse Company, as licensees of the Consolidated and Sawyer-Man Companies, have entered into a new contract with the Thomson-Houston Company, to take effect from the beginning of the present month, whereby all previous contracts have been cancelled, and a new license has been granted to the latter company to manufacture and sell lamps under the Sawyer-Man patents, but only for use in generating apparatus made by the Thomson-Houston Company. The practical meaning of this is that so far as the Thomson-Houston Company use the Sawyer-Man lamps, they can only do so in connection with the arc circuits and direct continuous-current incandescent lighting. It will be gathered, too, from the above, that the alliance between these two great companies, which at one time pointed so strongly to an even more general unification of competing interests, has been broken, and that, if anything, the rupture may become greater than it is now. The Westinghouse Company take occasion in this circular to point out that the development of the alternating system in the United States is almost wholly their work, and that they are entitled to the benefit of it, and that, on the other hand, the claims of the Fort Wayne Jenney Company to do an alternating business are mere pretensions and without foundation. Altogether the situation is an interesting one.

In my last letter I made some reference to the public trial of the Daft electric motor, "Ben Franklin" on the Ninth Avenue elevated road. This week the trip has been repeated with even greater success, the cars being filled with a large number of spectators who were kept away by the dismal weather on the previous occasion. It is stated that next week the "Ben Franklin" will draw a shuttle train regularly over the portion of the road upon which the experimental runs have been made (from Fourteenth to Fiftieth-street), and that the public will have the opportunity to make their journey for that distance by means of electricity. If this be true it will be a most important step in advance, for the feeling of the public towards electric motors is very cordial, on account of its many advantages, and the desire for an opportunity to ride behind them is freely expressed.

CORRESPONDENCE.

MAGNETISM OF STEEL NEEDLES BY LEYDEN JAR DISCHARGES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of October 5th, page 711, you printed for me a letter from Prof. Ewing, giving an ingenious explanation of the magnetisation of steel by the oscillatory current of a condenser discharge, as being due to a gradually lengthening period. You also printed a note from me pointing out that if the resistance of the spark gradually increased as the energy of the discharge died down, a gradually increasing period would be accounted for.

So far there is nothing to correct; but I went on to say that Feddersen had actually observed a gradually increasing period in the oscillations when he examined them in a rotating mirror. This statement Mr. R. E. Baynes, of Christ Church, Oxford, has been good enough to correct in a note to me, saying that according to his recollection of Feddersen's experiments the lengthening-out periods were obtained, not in the true vibrational spark, but in the intermittent spark which is often obtained when the resistance of the circuit is much too great for oscillation—such intermittence as degenerates into intermittent spitting when a piece of wood or something of that kind is included in the circuit. On referring to the original Papers of Feddersen I find Mr. Baynes' recollection precisely confirmed; consequently, I was wrong in saying that gradually lengthening periods of vibration have actually been experimentally observed.

Since then I have made a very large number of experiments on the magnetisation of steel needles, with the result that, without saying anything against their being magnetised reversedly in concentric layers, I have lost all faith in the direction of their *resultant* magnetisation being ever abnormal or different from what the direction of the discharge current would lead one to expect; in other words, I believe at present that what occupies so large a place in books as "abnormal magnetisation" has no existence. If this faith, or want of faith, should be justified by further experience, it will become a most puzzling thing to account for the mass of experimental material by which the facts of abnormal magnetism have been substantiated.—Yours, &c.,

OLIVER J. LODGE.

ELECTRICAL THEORY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I find that I have never replied to a question addressed to me in Prof. Silvanus Thompson's letter in your issue of November 16th, p. 54.

I have always meant by "displacement current" true variation of electrical displacement, and not a bodily conveyance of electricity. At the same time, displacement currents necessarily accompany the transfer of electric charges, and also every case of electrical flow in a so-called "unclosed" circuit; and the question is whether the magnetic effect admittedly caused both by conduction and convection currents is wholly caused by them alone in every case, or whether the variations of electric displacement contribute their share to the general effect.

That convection currents are as effective as conduction currents in producing a magnetic field is proved to my mind by the electro-magnetic effects of currents in electrolytes, as well by such experiments as that of Rowland. So far as I know no doubt has been expressed on this head.

But consider a stationary charged sphere suddenly connected to earth, the previously displaced electricity moves in radially in all directions without any whirl of any kind, perfectly symmetrical all round, except where the line of current occurs and disturbs the uniformity.

Now, in such a case as this, there is a conduction current along the wire to earth (or it might be a convection current, if connection were effected by a number of pith-ball-carriers instead of by a wire), and this line of current will admittedly have a magnetic effect; but is that the whole of the effect, or must the variations of displacement be taken into account in order to calculate the whole?

In all cases where electric displacement varies there must be a current of some kind somewhere flowing in an unclosed circuit. The question seems to be whether this current is precisely competent to produce all the magnetic effects observable, and no more.

Before the Bath meeting, I should have confidently given as my impression of the correct procedure (of course derived from Maxwell): Take *all* the currents into account, displacement currents just as much as any others. All are equally effective, and no such thing as an unclosed circuit has ever to be considered for any purpose whatever. Since the Bath meeting, I have not had time to go into the matter afresh, nor to give any real thought to it, and though my impression remains the same, it would be both useless and unseemly to express it without a great deal more consideration.—Yours, &c.,

OLIVER J. LODGE.

ELECTRIC TRACTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Your article on electric tramcar batteries, motors, &c., has decided us to send you herewith a plate from the car which has been running in Birmingham, and we do this to call your attention to its construction. We note your description of the plate of Mr. Reckenzaun, and also send you a plate of Dr. Frankland's, which we think has exactly the same qualities as portrayed in the Reckenzaun one. You will find the plate sent by us is cast from an ordinary chill, with a bevel in each direction from the centre to the outside, then treated mechanically to flange over the outer edges of the plate, thus forming a means of holding the paste firmly in the plate. We think you

Digitized by Google

will see the great advantages of this plate, as in accumulators for tramcar purposes the desideratum is to obtain the greatest possible discharge from a given weight of plates, the area of the active material being an important factor to this end. In the early Julien grids, as tried by Huber, of Hamburg (in whose experiments we were interested, as supplying him with motors, and other material, and also with Julien himself upon the Brussels Tramway, where we have supplied material, and still have orders on hand), the trouble was in the paste falling out of the grids, due to vibration, and the washing of the liquid in the cells, caused by the motion of the car. The oxidation of the grid does not become a factor, as the life of the battery, due to the previously-mentioned causes, is too short for oxidation to have any great effect. The hardened grids, as suggested in your article, due to Julien, we have also made from an early date, probably from as early a date as Julien himself, as we were casting these when he visited us, with a view to getting us to adopt mercury. We did not consider mercury an advantage, but as dangerous to our workpeople, and we venture to state our belief that it is not used in the casting of grids at the present time for this purpose.

We also note in your article that two motors are used upon the Reckenzaun car. In watching numerous experiments we have found that this has a great tendency for the cars to leave the rails, also that small electrical motors have not been found to have the efficiency obtainable from larger sizes, and they have double the liability to derangement. The mechanical mode of driving in this car will not commend itself to mechanical engineers, as the power consumed by this arrangement must be much greater than with simple gearing. The method of charging the field connections so as to be able to run with a varying field in the motor seems an ingenious contrivance for emptying the batteries without obtaining the energy in the form of work upon the car.—Yours, &c.,

For ELWELL-PARKER (LIMITED),
T. PARKER, Director.

Wolverhampton, December 18, 1888.

[We have received the plate referred to, and find that the construction of Dr. Frankland's plate entirely agrees with Mr. Parker's description, but it differs from the Reckenzaun plate in that the grid is of greater thickness; in fact, while the Reckenzaun plate has a thickness of only $\frac{1}{8}$in., Dr. Frankland's is a full $\frac{1}{4}$in. But the paste cylinders in the Reckenzaun plate are $\frac{3}{16}$in. in thickness, and project from the surface on both sides. In the Frankland plate, on the contrary, the paste is flush with the surface. The latter plate, owing to its thickness, is, of course, perfectly rigid, while the Reckenzaun plate, as we noted last week, may easily be bent round till the ends meet. The plate sent by Messrs. Elwell-Parker is in excellent condition. As to the use of mercury in the Julien plates, we expressed the same opinion as our correspondent on page 165 of our last issue.—ED. *E.*]

ELMORE'S ELECTRO-BURNISHING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I thank very much your correspondent, "C. J. S.," for his information as to conductivity of Elmore's copper, but I take this occasion to protest against the expression of the *specific resistance* in microhms, because it is not homogeneous. The specific resistance is given by the formula

$$s = R\frac{s}{l},$$

s being the specific resistance of a conductor of length *l*, section *s*, and resistance R. The dimensions of s are therefore

$$s = L\,T^{-1} \times \frac{L^2}{L}, \text{ or } s = R\,L.$$

It is the product of resistance by length, and should be expressed in *microhms-centimetres*, and not in microhms.

The specific resistance is not the resistance of a cube of one centimetre side, but is only *numerically* equal to that resistance. Analogous errors are very often found in denominations of physical quantities, because these denominations are calculated from units which represent these quantities instead of being derived from their physical dimensions, the dimensions being quite independent of choice of units.—Yours, &c.

GASTON ROUX.

Préparateur à l'Ecole de Physique et de Chimie Industrielles de la Ville de Paris, 91, Rue de Dunkerque, Paris, Dec. 17.

FAHRIG'S INFLUENCE MACHINE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: During 1880-84 I investigated the phenomenon of electrical influence in vacuum lamps, and came to the conclusion that the electrical phenomenon observed by exciting a lamp, although of great quantity, no known means exist to continue or to obtain tension. In 1882 I constructed a compound armature of these lamps, but failed to obtain tension "*spannung.*" The single-lamp armature, as per this copy, gives *best result.* It would be highly interesting to me to have the opinion of others upon these very instructive experiments. —Yours, &c. ERNEST FAHRIG.

ELECTRIC EFFECTS ON BEN NEVIS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The following extracts from a letter from Mr. Omond, superintendent of the Ben Nevis Observatory, may be generally interesting. It was in answer to a question of mine as to whether anything electrically noteworthy was observable at that elevation.—Yours, &c., OLIVER J. LODGE.

"We have, I am glad to say, very few thunderstorms on Ben Nevis, but when they do occur they are apt to be severe. Once or twice thunder-clouds have rested on the hill-top, and when these pass off again there is always a sharp crack like a pistol shot heard in the lightning conductor, and frequently sparks have been seen springing out from the stoves inside the building. The conductor is, I fancy, not connected with these sparks; but whether there is any discharge from the top of it at the same time I cannot say.

"The conductor consists of a copper wire rope, about 1in. diameter, ending in a rod of copper with four sharp points round it near the top. This rod is fixed to the chimney—that is, to the highest part of the building—and the other end of the wire rope connects with an earth-plate, bedded in clay near the observatory.

"The only electrical phenomenon of at all frequent occurrence is St. Elmo's Fire, the brush-discharge look of which is sometimes seen on the conductor, stovepipe, and other projecting bodies on the roof, including observers, while cyclones are passing in winter. A description and discussion (meteorologically) of this will appear in the next part of the Scottish Met. Soc. *Journal.* "R. T. OMOND.

"21st November, 1888."

COMPANIES' MEETINGS & REPORTS.

The Swan United Electric Light Company (Limited).

The sixth ordinary general meeting of this Company was held at the Cannon-street Hotel last Tuesday, under the presidency of Mr. J. S. Forbes.

The SECRETARY (Major S. Flood Page) read the notice calling the meeting, and the report of the Directors and statement of accounts were taken as read.

The CHAIRMAN, in moving their adoption, said in the course of his remarks: I think we had better first deal with the profit and loss account. You see there that the debtor and creditor account is presented in much the usual form. We begin with the stock of lamps and material taken over from the previous year. Then come the purchases connected with the manufacture of lamps during that year; the expenses of administration, wages, and expenses at the factory, depreciation, and the balance. On the other side of the account the substance is really in the item of sales, less commission and allowances. Then there are other items of transfer fees and interest, and the stock of lamps in hand and material at the end of the year. The most important item of the lot is the sales, less commission and allowances, £40,120. That shows a considerable advance in the volume of the business as compared with the previous year—about £13,000 in round figures. The item of transfer fees and interest account is somewhat less—about £330. The interest we derive chiefly from our investments and our cash. We have called up a certain amount of our capital, and we have in hand a good round sum, which is invested, £5,000 being in Prussian Consols, an investment which is obliga-

Digitized by Google

tory. The item of stock stands at £9,676, or £1,450 in excess of the same item a year ago. Adding these two sums together—what more we have sold and what more we have made and put away—there is about £14,150 more volume of business than we had in the previous year. On the other side of the profit and loss account the stock brought over at the end of last year stood at £8,221, and the purchases were £17,239. That is a compound item which embodies the material necessary to manufacture the large number of lamps sold, and it also includes a considerable amount representing lamps which this particular Company were obliged to buy of the Company in England in which we are so largely interested—the Edison and Swan Company. The wages and expenses at the factories were £11,923, and the depreciation is £1,079. The balance to the good is £8,332. That is the result of the year's working. The balance is only £780 in excess of that of the preceding year, and looking at the large additional volume of business, the analytical mind would want a reason for that small increase in the balance, which I can give. There is one happy feature in connection with the balance of £8,332 in that it is unencumbered by a claim for previous losses. In the year before we had a balance of between £7,000 and £8,000 of profit, but on writing down outstandings, in the shape of accumulated losses of previous years, that balance was reduced to £1,720. The proprietors may ask how it is that, having done £13,000 more business, we have only £780 more profit. I must tell you that competition is going on rather severely on the Continent—probably not quite so severely now since we ourselves have become members of a considerable Continental Company—but still it had gone on, and we thought it prudent to meet that competition by, in fact, bending to the storm of it, and reducing somewhat materially the price of the lamps, so that we have sold a larger number of lamps at a less price per lamp. Another reason for the small increase of profit is that in valuing the stock taken forward to next year we have been a little more severe against ourselves than we were a year ago. Being more anxious as to the permanent foundation on which this business is to rest than the profit of a particular year, we thought it prudent, in the face of a possible reduction of prices, to carry forward the stock at a less price. That has made a material difference in the figures, for we might have carried forward those lamps at a price of £2,000 or £3,000 more than we have done. If we have erred in what we have done it is on the right side. Turning to the balance-sheet, things remain pretty much as before. The capital is about the same, so is the item of forfeited shares. Sundry creditors figure at £2,943, or nearly £2,000 less than in the previous year. The balance from the previous year is £1,720, having been reduced to that amount by the writings off which I have explained, and then we have also the £8,332 which has been brought from profit and loss account, so that we have now standing to our credit in the balance-sheet £10,052. On the opposite side the cost of patent rights, as per last balance-sheet, stands at £105,852, increased by £930 by the expenditure on patent rights on the formation of La Compagnie Générale des Lampes Incandescentes. I explained at the extraordinary general meeting in June what we were doing with respect to the agreement with our French competitors. We have become a portion of the Company I have just mentioned, which has its seat in Paris, and this agreement has got rid of the litigation about the Swan and Edison patents. We appear in the balance-sheet as holding 800 fully-paid shares in the French Company, which is equivalent to the patents we put into that company. The £15,838 represents those 800 shares of 500fr. each, which we got as our proportion of the capital of that company—1,000,000fr.—representing the patents which both companies put into the common pot. That item of patent rights is thus reduced to £90,944. The outlay on factories, plant, &c., has been reduced from last balance-sheet to £8,396 by the realisation of plant, &c., to the amount of £193. Then this item is further reduced to £5,396 by a special reserve of £3,000 against depreciation. That £3,000 special reserve was made owing to our having an unsettled account at the Lille factory, which is now wound up and closed, and we have brought this £3,000 of reserve into the account in order to write down our outlay on factories and plant. Against the £5,396 we have made the usual depreciation out of revenue, and thus the item of outlay on factories, plant, &c., is brought down to £4,317. The only factory we have in hand now is at Kalk, near Cologne, on which a considerable sum has been spent from first to last. We have, however, written down the item to this £4,000 odd, which represents the value of that factory to us or anyone else to whom we may make it over. We contemplate extending to Germany the same arrangements we have been happy enough to bring about in most of the countries on the Continent. In that case we should probably make a fusion there, on the condition that the Kalk factory was taken over at a fair valuation, which I hope will considerably exceed the £4,317 mentioned. Then we come to our *bonne bouche*—the shares in the Edison and Swan Company, which figure at £208,478. Then the shares in the French Company stand at £15,838, and the 740 shares subscribed—meaning the subscription of capital of both companies to start the business there—represent £14,651, and the two together amount to £30,489, the amount of interest which we have got in that company. I am not going to prophecy, but our French colleagues, whom we saw recently in Paris, are very sanguine that the day is not far distant when there will be a fair dividend forthcoming on the outlay. 2,000,000fr. is not a large amount of money for which to have possessed all these patents, and to have started the business. They are already doing a good business. The item of sundry debtors—that is, people who owe us money—is reduced by £3,400 compared with that of last year, and we have no reason to expect any loss on the item. The stock on hand stands at £9,676, which is brought from profit and loss account, and which I have explained. Then come our investments, and you will see that in Prussian Consols, in Three per Cent. and New Two and-Three-quarter per Cent. Consols, and in cash we have nearly £40,000, so that we have a not inconsiderable sum if we want it to further extend our business. The two first paragraphs of the report embody all that I have told you. All the legal formulæ have been carried through with regard to the agreement between the Compagnie Continentale Edison, and which has resulted in the formation of La Compagnie Générale des Lampes Incandescentes. That company is on its legs, and the factory which they are erecting was practically designed by our friends in London. Meanwhile we are supplying them with lamps, partly from this country and partly from Germany, until they are in a position to manufacture them, which I daresay they will be next February or March. We state that the litigation as to the Swan and Edison patents is still dragging on in Germany; but we hope to bring it to an end. That, however, turns on whether the negotiations are successful, and whether the Germans will be disposed to follow the lead that we have shown them in France, so as to put our forces together and stop the litigation. We have been most anxious for the last two or three years to get rid of the litigation, and to do what has turned out wise in this country, and which I think will be wise there. Two Directors retire by rotation—Mr. J. W. Swan and Mr. C. H. Stearn. With respect to Mr. Swan, I apprehend that there will be no question as to the wisdom of re-electing him. As to Mr. Stearn, the position of our business in Germany and the possibility of its being absorbed within a short time by some other company, have brought us to the conclusion that it is not necessary or desirable that Mr. Stearn should be re-elected a Director. It may be both desirable and necessary to retain him in some other capacity, but not as a Director, and as we do not know what may happen when this fusion takes place, I dare say the best policy would be to keep that vacancy open for the present. Messrs. Quilter, Welton and Co., the auditors, retire. Now there is only one other matter which I should like to draw your attention to—what are we to do with this £10,000? I should like to take a little of it as the interest on the shares which I hold in this Company; but humanity is weak in some things. It appears to us that it is not prudent at present to distribute it, for the same reason that in the Edison and Swan Company, where the balance was very much larger—£25,000—we thought it necessary to carry it over for the present. The litigation in Germany involves the possibility—I am not going to say how remote that possibility is—but still there is the possibility of our being landed in damages, and it would hardly be prudent to part with the funds out of which those damages would be fairly met if they arose. I do not, however, want to alarm anyone in regard to that matter. If the litigation is put an end to on the same basis as it was in connection with the French Company, we shall have our £10,000 undiminished. I cannot imagine, from what I know of German law, or the probabilities of German law, the damages amounting to anything like £10,000; but it is an indefinite quantity. And then there is another reason. This Company of ours is an English Company, and we are advised that it is forbidden by law to distribute a dividend where there is what is called a "wasting" quantity, such as the cost of the patent rights. We have got rid of that portion of the patent rights which affects a considerable part of Europe, and there is a certain residuum left. We have got Germany, India, and the Cape, and some outlying places, but it is quite impossible to apply to Germany, India, or the Cape, in a concrete form, any portion of the £90,000. Meanwhile, with that £90,000 standing in our balance-sheet, we are advised that we cannot distribute a dividend. That is how we are advised, and, being so advised, it would be exceedingly rash, not to say imprudent, to attempt to distribute it. What I think may possibly arise may be this—what would in any case be a prudent thing to do. These patent rights have a certain time to run, and what we are trying to do in this Company and in the Edison and Swan Company is to so conduct ourselves by utilising the period in the improvement of the lamps, the production of the very best article, the extension of our connections, the founding of a going concern, and the having a good trade mark, as to be comparatively independent of patents or protection when the time arrives. I think the law is rather shadowy upon us, but we had better err on the safe side, and I for one should be prepared to recommend you to do one of two things, or both—out of any large profit to put aside a portion of it, and also to consider whether it would not be wise to do what the Courts of Law will allow us to do—reduce our capital. Assuming for the moment that the policy of setting aside any of the £10,000 against the expiring of the patents was not desirable, then it would be desirable if we could to distribute a dividend; but the law says you must not distribute anything as dividend until you have written down these patent rights. But you can write down your capital. Now, writing down the capital is a purely theoretical proceeding. It does not matter to us two straws whether our shares represent £3. 10s., £3, or £2. 10s. if the holders of these shares are entitled to all the profit made. It is simply a question whether the dividend shall be 5 per cent. on one figure or a larger per cent. on a smaller figure. You still remain the owners of all the property. That seems a plain and easy solution, and is a legal plan of relieving us of the embarrassment of locking up our dividend when we want to pay it. We should have to call a meeting for the purpose of doing that; but I am only now throwing it out to-day for the sake of preparation, and as a reason why, if the Directors were ever so anxious to recommend you to distribute this £10,000, they could not do so. He concluded by moving the adoption of the report and accounts.

The DEPUTY-CHAIRMAN (Mr. F. R. Leyland), in seconding the motion, said he fully concurred in what the Chairman had said respecting the balance in hand of £10,052. There was the possibility of their having to meet the costs of the litigation in Germany, and they could not persuade themselves that the patents they had now represented anything like the value at which they stood in the balance-sheet of £90,000. If they did not represent £90,000, it was quite clear they had only two courses open to them—either to replace the loss of capital by accumulating their profits until the loss was balanced, or to apply to the Courts for reducing the capital.

The CHAIRMAN invited discussion, but no shareholder rising to address the meeting, he put the motion and declared it carried unanimously. Continuing, he proposed the re-election of Mr. Swan, observing that that

Digitized by Google

gentleman's reputation was European. There could not be a doubt that Mr. Swan being largely interested as a shareholder in the Company, and having such enormous scientific attainments, would be a most desirable colleague on the Board.

Mr. PELL seconded the motion, which was carried unanimously.

Messrs. Quilter, Welton and Co. were re-appointed auditors, and the proceedings then terminated.

The Pilsen-Joel and General Electric Light Company (Limited).

An extraordinary general meeting of this Company was held on the 14th inst., at the Cannon-street Hotel, Sir Rawson W. Rawson in the chair, for the purpose of considering, and, if thought fit, passing the following resolutions:—

"1. *That the Company be wound up voluntarily, under the provisions of the Companies Acts, 1862 to 1886.*"

"2. *That George Shead, of No. 9, Laurence Pountney-hill, Cannon-street, in the City of London, chartered accountant, and William Henry Trentham, of No. 4, Stanhope-street, Euston-road, engineer, be and are hereby appointed joint liquidators for the purpose of such winding up.*"

The SECRETARY (Mr. W. H. Trentham) having read the notice calling the meeting,

The CHAIRMAN stated that in what the Directors proposed they were acting upon a recommendation passed at the recent ordinary meeting. They had called the shareholders together to take the necessary further steps, and it was now for them to carry out what appeared to be the wish of the large majority of the shareholders at the late meeting. He concluded by moving the first resolution, as above.

Mr. G. L. WHATELY seconded the motion.

Mr. FELLOWS thought it was wrong for the Directors and shareholders to forego all control over the property of the Company, and to hand it over to two persons to dispose of as they might think proper. He suggested that the further consideration of the matter should be adjourned for two or three months. He eventually proposed the adjournment of the meeting for two months for this purpose, and to see if some offer could not be obtained so as to submit a definite scheme when it was decided to go into voluntary liquidation. His object was that they should liquidate with a definite scheme before them, and not hand over the business into the hands of two irresponsible persons, however able they might be.

Mr. FYFE seconded the amendment. He objected to the passing of the resolution at the present stage, because he considered that he had not had a proper opportunity for endeavouring to procure a customer. He had brought a customer to the factory, but the Directors and the Secretary told him that he had no authority from the shareholders or the Board to carry out his views. He brought a customer who was perfectly able and willing to buy the property, but when he saw there was unwillingness on the part of the Directors to effect a sale through him (the speaker) he had declined to go further into the matter. He still thought that if the proposal were adjourned for a month or two he could get a better offer than that submitted by Mr. Gwynne at a former meeting.

Mr. WHATELY, in reply, said that if they had accepted Mr. Gwynne's offer, which was rendered nugatory by Mr. Fyfe's action, they would have had 4s. a share returned to them. If they went into voluntary liquidation now they would probably get something back. If they postponed it for two months they would get nothing. If they postponed the consideration of the matter for six months they would probably have to pay a call, because several influential shareholders had threatened that if voluntary liquidation was not entered into they would move for a compulsory winding up.

After some further discussion, the amendment was put to the meeting and lost on the show of hands, and the original resolution was afterwards put and carried.

The CHAIRMAN subsequently proposed the second resolution for the election of Messrs. Shead and Trentham as liquidators.

The motion having been seconded,

Mr. FELLOWS objected to the appointment of the two gentlemen proposed, and moved the election of an official liquidator. He was informed, however, that it was not competent at that meeting for such a resolution to be brought forward.

The motion was then carried.

Woodhouse and Rawson (Limited).

An extraordinary general meeting of the shareholders of this Company was held on the 14th inst., at the Cannon-street Hotel, under the presidency of Lieut.-Gen. Sir John Stokes.

The SECRETARY (Mr. J. Shurmer) having read the notice convening the meeting.

The CHAIRMAN said: This meeting is called, though not strictly necessary, in order that we may have confirmed by you the auditors that we have temporarily appointed, and also in order that we may let you know the arrangements that are in progress with reference to the extension of the business, and have your confirmation of the same. You will be glad to hear that since we had the pleasure of meeting you some six months ago, we have gone on improving the organisation of the Company, which is now in good working order. In our installation department we have during the past year done work for Messrs. Peak, Frean and Co., the London Stock Exchange, Lord Brassey, Messrs. Guinness and Son, Messrs. Crosse and Blackwell, Drapers' Hall, Exeter Asylum, Messrs. W. H. Smith and Son, the Institute of Medical Electricity, and many other important firms and companies, and we have at the present time in hand orders for lighting the Palace of Mysore, from Sir Frederick Carden, and Messrs. J. W. Benson and Co., for extensions at the Drapers' Hall, and installations of varying degrees of importance. We are also in negotiation at the present time for the subcontract for lighting one of the most important districts of London, which subcontract we expect will come to considerably over £100,000. In our subsidiary Company working in Bradford, besides having put up installations throughout the district there are a number of establishments being fitted up by them, there being over twenty places in Bradford, such as the six principal banks, &c. Besides this large increase in our business there has been a striking advance in electrical business generally, and, as far as we can judge, there is likely to be a still greater increase. To give an idea of this growth it may be mentioned that we have not yet in any way felt the large increase that there will be in electric lighting derived from such companies as the London Electric Supply Corporation (Limited), with its large works at Deptford, the Metropolitan Electric Supply Company, and many of the other central stations that are being now started. It must be recollected that Woodhouse and Rawson (Limited) and its subsidiary companies lay themselves out for working for companies of this description, and that we hope to obtain a large amount of work resulting from their increase. To give an instance of the extraordinary increase during the last six months, we may mention that the turnover in electrical supplies of the Woodhouse and Rawson Electric Supply Company of Great Britain (Limited), one of our subsidiary companies, which does a merchant's business in buying and selling electrical goods and goods connected therewith, has increased nearly threefold. Foreseeing this increase some little time ago, the Woodhouse and Rawson Electric Manufacturing Company consulted us with regard to the extension of their Company, as they quite saw that the company in its existing state would be unable to cope with their business, and it was arranged to enlarge the company. As an instance of this increase, I may mention that they recently received an order for over 100,000 switches, the largest order ever given out. They also are in negotiation at the present time for an order for 200,000 incandescent lamps, and even at the double rate of their present turn-out, these two orders would fill them up with work for many months to come in their respective departments. The Manufacturing Company also wished to obtain the advantage of an amalgamation with another well-known business in the North of England, which also had a very great increase of business and was about to enlarge. We were in negotiation also ourselves for the purchase of various properties which we considered of value to our business, and on finding that the Manufacturing Company intended themselves to increase, we suggested their acquiring the properties we were in negotiation for. At this date there had been negotiations for some time between the Company and Mr. Rawson for the purchase of the founders' shares, as it was quite evident that should the business go on as we expected it was advisable for the Company to exercise its option and purchase the founders' shares. Our legal adviser told us, however, that it would be almost impossible to do this without the formation of a new company, as the Company could not purchase its own shares. Under these circumstances we considered it advisable to make an amalgamation, and we found that several other companies would be willing to join us. It may take a little time to complete this arrangement, but we wish to have the support of your approval to our doing this on the basis that the shareholders receive a bonus upon the amount paid up on their shares, and that there would be certain assets left in our hands from which we hope considerably to increase this bonus. At the present time we are paying dividends at the rate of 12 per cent. per annum, and we hope that by this amalgamation we shall be enabled to considerably increase this dividend, as we shall not then be obliged to set aside the large amount we now have to pay to the founders' shares. As you can quite see, it will not do to give any details of this amalgamation until it is further forward. You may recollect that at the meeting about six months ago I stated that we had just completed an arrangement of great importance to us. I am glad to say that this arrangement is now finally completed and in every way carried through, but I am not yet at liberty to divulge the same, as the interests at stake are too important. There is a company coming out in a short time called Elmore's Patent Copper Depositing Company (Limited), to work a process which we ourselves, as well as the most eminent experts of the day in such matters, consider one of the most valuable inventions discovered for a long time. We have been engaged in this for the past few months, and feel confident of making a large profit from the same. With regard to the matter of auditors, the late Mr. William Spain had, before this Company was formed, acted for Messrs. Woodhouse and Rawson, and his firm, Messrs. Spain Brothers, were appointed as auditors to our Company. We regret to have to say that since our last meeting Mr. William Spain has died, and we have appointed as auditors to the Company Messrs. Chandler, Pixley and Co. and Mr. Champness, who until shortly after Mr. Spain's death was a partner in the firm of Messrs. Spain Brothers, and who attended to Mr. William Spain's work. Messrs. Chandler, Pixley and Co. are well-known auditors, and are already auditors to one of our subsidiary companies. It is necessary to have this appointment confirmed. The first motion that I have to put to the meeting is that Messrs. Chandler, Pixley and Co. and Mr. Champness be appointed auditors.

Mr. HAYES seconded the motion, which was agreed to.

The CHAIRMAN: I have stated in my address that we seek for the moral support of the meeting to do that which we have the power to do. Seeing it is a matter of so much importance we prefer to have the confirmation and approval of the body of the shareholders as to our amalgamating the Woodhouse and Rawson (Limited) to a large company, which will give us a wider field of action, and hold out every prospect of success.

Mr. RAWSON, in reply to Mr. Hayes, said that the interests of the shareholders would be carefully looked after by the Directors, who were amongst the largest shareholders, holding between them a very large proportion of the share capital. They had done everything they could to make the new company such a company as would both command the work that was necessary for such a company, and that would also bring in, as the Chairman had stated, a larger dividend probably than was paid even now that being done by obliterating the founders' shares. In reply to Mr.

Digitized by Google

Reed, he thought it would be necessary for the company to go into voluntary liquidation. The only objection to that course was that statements got into the newspapers that such and such a company was being wound up; but he thought that in their case everyone would know that it was only being wound up because of the business being taken over by the new company.

A SHAREHOLDER said he thought they were entitled to some more information respecting the new company. No other information had been given than that the company was proposed to be amalgamated with a larger company, and, for his own part, he would like to know more.

Mr. RAWSON, at the request of the Chairman, replied, stating that the difficulty with respect to giving details was that at the present time, though some of the agreements were practically completed, those interested in other businesses that were coming into the amalgamation were holding out for terms which were considered by others unfair, and if they knew what terms Woodhouse and Rawson (Limited) were getting they would be in a stronger position to ask for a larger sum than those connected with the amalgamation were prepared to give them. It was always undesirable prematurely to disclose details with respect to such a business. He did not suppose that the Chairman would have any objection to state privately to any shareholder what the arrangements were, and he (Mr. Rawson) believed that when the shareholders heard the arrangements they would consider them very beneficial for the Company.

The SHAREHOLDER said it seemed to him that they were going to take a jump in the dark, and they did not know whether their shares were to be sold to the new company at par or a discount. Only one meeting had been held, where an interim dividend was paid at the rate of 20 per cent., which took many months to pay, and at the time of that meeting it was said that there was enough in hand to pay 40 per cent. They were called upon now to sanction a matter of importance, but they did not know what the terms were.

The CHAIRMAN said he had stated in his opening address that the shareholders of the present Company would receive a bonus on their present shares, and a considerable bonus, too, so that there was no question as to their shares going at a discount.

A SHAREHOLDER asked how it was, in the face of the statement just made by the Chairman, that one could not readily sell the shares on the Stock Exchange at par.

The CHAIRMAN replied that he knew nothing about operations on the Stock Exchange.

Mr. RAWSON pointed out that the shares were so few in number. There were only 18,000 of the partly paid shares, and the total amount of the share capital on which the Company had to pay a dividend was only something like £70,000. They could not get a quotation yet, and people who wanted to buy or sell their shares had to wait until an opportunity was afforded by some other person requiring to buy or sell shares, as the case might be. At the same time, about three weeks ago one of the principal brokers on the Stock Exchange went to him (the speaker) and asked him as a favour to let him have some of the speaker's partly-paid shares on loan for a short time, the broker having sold some shares to a client abroad who had not sent in the certificates of transfer, and as he was unable to buy the shares in the market, they were going to buy them in against him. He (Mr. Rawson) lent the shares. Almost immediately afterwards he heard that there some were shares to be sold on the Stock Exchange, and a friend of his wrote and told him that he had given instructions to his broker to purchase, but the broker said that they were only offered for a very short time, and that they had been taken off the market. One benefit they would get by extending their Company, as was now proposed, was that they would get a quotation, and the buying and selling of the shares would then be greatly facilitated.

A SHAREHOLDER presumed that the Directors were not asking the meeting to do more than approve in principle the proposal, seeing that they had practically no information respecting it.

The CHAIRMAN: Naturally, when no details are submitted to you we are only asking you to approve of the matter in principle. The details will be submitted to you at a future time. In regard to the bonus, that will be taken by the shareholders in cash or shares in the new company at their option. He added that before the accounts could be submitted they had to be passed by the auditors, and it was necessary to obtain the shareholders' approval to the nomination of auditors, so that the accounts might be presented, which would be done before the close of the year. Having to call a meeting for the appointment of auditors, they had thought it right to mention the scheme generally that was on foot in the shareholders' interests. He then put it to the meeting whether in principle they desired to support the Board in amalgamating with other companies to form a larger company to carry on the business in hand, and the same was carried unanimously.

Mr. RAWSON said that an important shareholder had urged a point of considerable interest to those who held partly paid shares. By the agreements to which reference had been made, the present proposal was that the shareholders of Woodhouse and Rawson were to have a bonus of so much per cent. in the new company on the amount that was paid up on their shares at the date of handing over the business of the Company; and, in addition, the directors were to keep certain assets and realise those assets, distributing the proceeds among the shareholders in proportion to the amounts paid upon their shares. The pith of that arrangement was this, that to the shareholders of Woodhouse and Rawson at the present time it did not matter how much was paid up on the partly paid shares so far as regarded the bonus they were to receive from the new company, because all the shareholders in Woodhouse and Rawson (Limited) would participate alike—they would get the same percentage; but with respect to the assets left in the hands of the Company for distribution among the shareholders, the amount that each shareholder would receive on his shares would be determined by the amount paid up upon the shares; and the shareholder to whom he (the speaker) had referred, who held partly paid-up shares, maintained that it was unfair that the shareholders who had borne the brunt and burden of

the day a year or 18 months ago, when it was not known whether the Company was going to be a success or not, should not participate in the same way as the holders of the vendors' shares. It would make a great difference to Mr. Woodhouse's executors and himself, but as regarded himself he had agreed with the Board that if any of the holders of partly paid shares agreed to pay up all their shares before the arrangement was concluded they could do so, and in that case they would participate fully in the amount of assets to be divided.

Mr. REED asked whether the dividend earned by the Company would be passed over to the new company?

Mr. RAWSON replied that the dividend which had been earned up to the 30th June would be paid to the shareholders when the auditors had gone through the accounts and the matter had been agreed to at the general meeting.

The CHAIRMAN observed that an interim dividend had been paid to the 31st Dec. last.

Mr. RAWSON said that the dividend due up to the 31st inst. would probably be sunk in the bonus, but they could not tell yet. The profit they would make by the copper depositing company was claimed by the new company, and they would have to give that up. Those who paid up now in full their partly paid-up shares would not get a dividend for the past six months, but only from the time the amounts were paid up, and the dividend that was going to be paid would be up to the 30th June.

A SHAREHOLDER inquired whether the shareholders whose holdings were not fully paid up were to pay them up in full before they participated in the bonus?

Mr. RAWSON: No. It is at their option to pay up in full. They will receive *pro rata* according to what is paid up.

The proceedings then terminated.

Maxim-Weston Electric Company (Limited).

An extraordinary general meeting of this Company will be held at the Cannon-street Hotel, E.C., this day (Friday), at 2 o'clock, when the resolutions which were passed at the extraordinary general meeting of the Company held on the 3rd December last will be submitted for confirmation as special resolutions.

An extraordinary general meeting of the Company will be held immediately after the extraordinary general meeting announced above, when the following resolutions will be proposed as special resolutions:—

1. *"That the liquidators of the Company be and they are hereby authorised to consent to the registration of a new company to be named the Maxim-Weston Electric Company (Limited), with a Memorandum and Articles of Association which have already been prepared with the privity and approval of the Directors of this Company.*

2. *"That the draft agreement submitted to this meeting, and expressed to be made between this Company and its liquidators of the one part, and the Maxim-Weston Electric Company (Limited), of the other part, be, and the same is hereby approved, and that the said liquidators be and they are hereby authorised, pursuant to Section 161 of the Companies Act, 1862, to enter into an agreement with such new company (when incorporated) in the terms of the said draft, and to carry the same into effect with such, if any, modifications as they think expedient."*

NEW COMPANIES REGISTERED.

THE BRITISH ELECTRIC TRAMWAYS AND GENERAL SYNDICATE (LIMITED).—Registered by J. C. St. A. Angove, 27, Chancery-lane, London, W.C. Capital £10,000, divided into 2,000 shares of £5 each. Object, to promote, make, and provide, purchase, acquire, and dispose of railways, tramways, and other ways in the United Kingdom, and to equip, maintain and work any of such ways belonging to the company. The first directors shall be J. W. Haynes, and two others to be elected by the shareholders, and shall each hold 10 shares. The remuneration of the directors is not stated.

DOUSE'S PATENT FIRE CHECK COMPANY (LIMITED).—This company was registered on the 7th inst., with a Capital of £100,000, divided into 85,000 Preferred shares, and 15,000 Deferred shares of £1 each, to acquire the letters patent granted to Thomas Ralph Douse, for the manufacture of fire checks, and apparatus, and machinery therefore; to carry on business as a manufacturer and vendor of fire checks, and all material and apparatus necessary for making the same. The first subscribers are:—

	Shares.
T. R. Douse, Chatham, manufacturer	1
George Pepper, Chatham, chartered accountant	1
B. K. Wilson, 32, Bedford-place, Russell-square, W.C., law student	1
R. H. B. Wilson, Fritton, Norfolk, solicitor	1
H. J. Welch, 30, Stamford-street, S.E., clerk	1
J. V. Turner, M.E., 10, Credon-road, Rotherhithe, S.E.	1
H. Baines, 97, Harbut-road, Clapham Junction, S.W., electrician	1

There is not to be less than three, nor more than eight directors, and the first are to be appointed by the subscribers; qualification, 100 shares in the capital of the company; the remuneration to the directors is to be the sum of £500 per annum, or such larger sum as shall be equal to £100 for every 1 per cent. dividend over 15 per cent. per annum, but such remuneration is not to exceed £1,000 per annum. Registered office, 11, Gresham-street.

CITY NOTES, &c.

ANGLO-PORTUGUESE TELEPHONE COMPANY.—Coupon No. 2 of the Six per Cent. Debentures of this company, due January 1st next, will be paid, less income-tax, on and after that date by the Alliance Bank, 2, Bartholomew-lane, E.C.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended December 14th, 1888, amounted to £5,627.

EASTERN TELEGRAPH COMPANY (LIMITED).—This company announces the payment on 14th January next of interest at the rate of 3s. per share on the Preference shares of the company, less income-tax, for the quarter ending 31st December, 1888, and on the same day an interim dividend will be paid of 2s. 6d. per share in respect of profits for the quarter ended 30th September, 1888, on the Ordinary shares of the company, free of income-tax. The register of transfers will be closed from the 7th to the 14th January, 1889, both days inclusive.

EASTERN EXTENSION, AUSTRALASIA AND CHINA TELEGRAPH COMPANY.—This company declare an interim dividend for the quarter ended 30th September last of 2s. 6d. per share, being the same as a year ago.

SOUTH OF ENGLAND TELEPHONE COMPANY.—An extraordinary general meeting of this company was held at Winchester House, 50, Old Broad-street, London, E.C., on Thursday, the 13th inst., for the purpose of considering and, if approved, of confirming, as special resolutions under the Companies Act, 1862, the resolutions which were passed at an extraordinary general meeting of the company, held on the 22nd November, 1888. The meeting was presided over by Mr. D. Owen Bateson. The resolutions, which will be found set out in our issue of November 23rd, were proposed by Mr. Bateson and seconded by Mr. M'Gregor, and were carried unanimously.

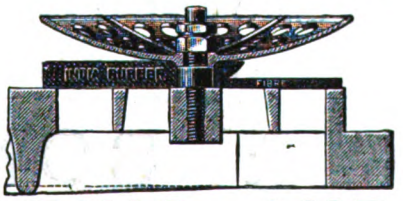
TELEPHONE COMPANY OF AUSTRIA.—Coupon No. 6 of the Five per Cent. Debentures of this company, due January 1st next, will be paid, less income-tax, on and after that date by Messrs. Martin and Co., 68, Lombard-street, E.C.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended December 14th, 1888 (after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, Limited), were £4,695.

CHANGE OF ADDRESS.—The offices and show rooms of the United Electrical Engineering Company will be removed on and after the first of the year to 3, Princes-mansions, Victoria-street, Westminster.

NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature. Suitable for any shaped guards. Only one quality manufactured.

"12, John-street, Sunderland, 26th Sept., 1885.

"DEAR SIRS,—In reply to your letter of the 25th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue to get them from you as required.—Yours faithfully, JAMES WESTOLL."

ENDLESS TELEGRAPH PAPERS.

(As supplied by Waterlow and Sons, Limited, to Her Majesty's Postal Telegraphs.)

These Papers are kept in stock in large quantities, and can be cut to any width for the **MORSE, WHEATSTONE, HUGHES,** and other machines; also the **RECORDER** Printing Paper, as used on the various Electric Automatic Printing Instruments.

COLLOTYPE PRINTING.

High class Reproductions in Facsimile of Monochrome Drawings, &c., specially useful for the Illustration of Trade Catalogues.

PHOTO-INTAGLIO ENGRAVING ON COPPER; PHOTO-ZINC ETCHED BLOCKS.

Photo-Lithography and Photo-Engraving and Printing in all its branches.

WATERLOW & SONS, LIMITED,

27, GREAT WINCHESTER STREET, LONDON, E.C.

VULCANITE

SHEETS, RODS, TUBES, CELLS, &c., for Electrical Purposes,
MANUFACTURED BY
THE NORTH BRITISH RUBBER CO., LIMITED.
EDINBURGH; LONDON, 57, Moorgate-st.; MANCHESTER, 6, Charlotte-st., LIVERPOOL, Cereal-court; GLASGOW, 106, Buchanan-street.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 554.—Vol. XXII. FRIDAY, DECEMBER 28, 1888. Price 4d.

NOTES.

If central station electric lighting is to undergo that rapid development for which almost every other circumstance is now propitious, it is practically certain that in very many cases the local authorities will have to give their consent, tentatively and temporarily at least, to the erection of a certain amount of overhead wiring. This fact is, of course, already widely recognised; but at the present juncture it is most desirable that it should be brought clearly before the public—or at least the official—mind. Fortunately there need be no hesitation or misgiving in so doing, since we can point to the splendid record of a London company which has for a period of nearly four years maintained a network of overhead electric light wires—extending now to more than 100 miles—without giving rise to a single mishap. Electric light cables are not pretty things, it must be confessed, but (provided always that they are properly erected) that they will become a source of appreciable insecurity to the public we must and do emphatically deny. That the danger arising from overhead wires in general is simply infinitesimal is a fact which was recognised by the Committee of the House of Commons who had the subject under consideration in 1885. And we may be at least certain that electric light lines will be both more carefully erected and more thoroughly looked after than either telephone or telegraph wires.

On the other hand we fully recognise that, as a rule, the function of overhead wires in electric lighting should be merely tentative, and that as soon as ever the supply company has ascertained that the degree of custom on any particular route will justify the expense, underground mains should, as far as possible, be substituted. But for the pioneer work of supplying a customer here and there and for opening up new districts the comparatively cheap and equally effective overhead line is, from a commercial point of view, absolutely indispensable to any really extensive and important scheme; and we cannot too much insist upon the fact that the commercial side of the question is the most essential of any, and no reasonable success can be expected where it is ignored or overridden by the authorities. Of course wherever resort is had to the early methods of low-tension distribution in limited areas these remarks do not apply with quite as much force; but even here practical experience, as at Kensington Court, for instance, has fully shown the advantages of this method of procedure. The wisdom of the general policy which we have indicated is fully recognised by the company whose operations in London are on the most extensive scale, and we believe that the London Electric Supply Corporation are willing to guarantee to remove every one of their overhead lines within either two or three years of its erection.

We have often indicated our views on the general question of overhead wires, insisting more especially that they should be placed under legislative sanction and control; but we have been induced to recur to the subject this week in part by the fact that in Birmingham, where a sub-committee of the Corporation is about to adjudicate on several electric lighting proposals, the local press, or a part of it, is evincing a very strenuous opposition to overhead wires. The *Birmingham Daily Post* of December 20th contained an article which can only be regarded as an *ex parte* statement on the subject, and in the interests of municipal progress, no less than in the electric lighting interest, we trust that the Corporation will not come to a hasty decision, which will infallibly retard the advancement of a beneficial movement whose full value has yet perhaps to be appreciated. Possibly the committee may be able to take some hints for dealing with the question from what has been said above.

The answers elicited from the President of the Board of Trade in Parliament last week by Mr. Watt and Mr. Rowntree were not so explicit as might be desired, leaving still unsolved some doubts as to the powers of the Board in respect to the action of Electric Lighting Companies competing in one and the same area. As, however, the President admits it to be the duty of the Board of Trade to consider objections—not only those to which their attention is called, but those "which may occur to them"—it is satisfactory to the several companies whose works are in progress in the parish of Kensington that no objection has yet occurred to the Board to warrant their interference; nor did the hostile questioning of Mr. Rowntree appear to suggest any to the President's mind. He probably thinks, and rightly, that the best judges of their own interests in a matter of that kind are the undertakers themselves.

In a recent number of *La Lumière Electrique*, M. Paul Hoho examines the theoretical conditions of the system of so-called "battery transformers" (such as that proposed by Mr. Crompton in *The Electrician*, April 13th, 1888, p. 636, and carried out by him at the Vienna Opera House), in which the whole of

Digitized by Google

the cells are charged in series, while the battery is divided into sets, each of which feeds a certain portion of the lamps, so that the charging current is divided between the cells and the external circuit. In the Vienna installation, for instance, we learn from Mr. CROMPTON (*loc. cit.*) that during about five hours two-thirds of the current goes direct from the dynamo to the lamps, but that when the demand is at a maximum this proportion is reversed. Now, for such a system M. HOHO points out that the dynamo current which traverses the parallel circuit (the battery and the lamp) is at any moment the same for each double section—since the sections are in series this is sufficiently obvious. It is equally clear that the number of ampere-hours absorbed in a given time in any double section is the same for all. But the portion of the charging current passing through any section of the *battery* at any moment is inversely proportional to the number of lamps burning at the time; whilst, on the other hand, the amount of current taken *from* the cells varies directly with the number of lamps.

FROM both these causes it follows that unless the number of lamps alight is always the same in each section, the batteries will acquire differing charges, and eventually some of the cells will tend to be run out whilst others are nearly fully charged. This state of things is hastened by the fact already indicated, that while the discharge is going on the battery which is being most rapidly discharged is the very one which is receiving the slowest charge. It is impossible to deny these obvious conclusions, but their practical importance may, no doubt, easily be overestimated. By interchanging the sections of the batteries and lamps, and by so arranging the rate of charge that time is allowed for charging some sections longer than others, much may be done to minimise the difficulty. For this, however, reliance must be placed upon the watchfulness and skill of the attendant in charge, and nothing but practical experience can prove the real value of the system. Mr. CROMPTON'S practical experience in Vienna has now extended over nearly another twelvemonth since he last communicated the results. And since somewhat conflicting rumours have lately arisen as to the later experience, it would be perhaps as well if he were before long to avail himself of an opportunity to report further.

ON February 16th of the present year, during the discussion at the Society of Telegraph-Engineers of Mr. KAPP'S Paper "On Alternate-Current Transformers," Prof. AYRTON, after describing the method of using an electrometer for the measurement of the power expended in an alternating-current circuit (see *The Electrician*, February 24th, 1888, p. 421), mentioned that this idea occurred to him first whilst listening to a Paper by M. JOUBERT during the Paris Exhibition of 1881. On coming away he said to Prof. FITZGERALD that he had just thought of a means of measuring alternating watts. "So have I," said FITZGERALD; and on comparing notes it appeared that their ideas were identically the same. But M. LEDEBOER, in *La Lumière Electrique*, now points out that, on the principle that the date of a discovery is the date of publication, the credit must in this case be assigned to M. POTIER, who published it in the *Journal de Physique* of October, 1881. We also find that this reference is given by MASCART and JOUBERT in their standard work on "Electricity and Magnetism."

IT will be remembered that the method in question involves two separate readings, and hence it is useless for continuous indication. This defect has been removed by MM. BLONDLOT and CURIE, who have constructed an electrometer in which the two opposite halves of the aluminium needle are insulated from one another. There are two pairs of semi-circular "quadrants," one above and one below the needle, and in order to damp the oscillations they are made of steel and magnetised. When used as a wattmeter the upper and lower plates on the same side are respectively connected together, and each pair is also connected to either end of the conductor (which may or may not possess inductive resistance), in which the expenditure of power is to be measured. The two halves of the needle are connected to the two ends of a non-inductive resistance, which has to be placed in series with the other conductor. The deflection is then directly proportional to the energy expended in the latter per unit of time. Calibration for alternating currents may easily be effected by means of a direct current.

IN connection with continuous currents the wattmeter is a very unimportant instrument, but we take it that with alternating currents the case is different. Such an instrument may or may not be useful in everyday working, but in many experimental and constructive investigations a trustworthy alternate-current wattmeter would be of the greatest service. The instrument just described is evidently an improvement upon the earlier arrangement, but it is still open to some objections. It may or may not be of consequence, in a given case, that a certain amount of power must be fruitlessly expended in the non-inductive resistance; although the smaller this waste is made, the smaller is the deflection to be read. Moreover, in the discussion already alluded to, Prof. AYRTON said that he had had the unhappiness to discover that quadrant electrometers were subject to a certain, or rather uncertain, coefficient of aberration, which rendered the theoretical formula inapplicable. On this point he promised further information—a promise which has yet to be fulfilled. It is to be hoped that the new instrument of MM. BLONDLOT and CURIE may prove to be free from this difficulty.

SOME of our readers will probably remember the interesting experiment of M. FOEPPL (*The Electrician*, June 1st, 1888, p. 105), in which he submitted Prof. EDLUND'S theory of the conductivity of a vacuum to what would appear to be a crucial test. He built a galvanometer with coils of glass tubing, and connected this with an induction coil in which the secondary coil also consisted of glass tubing, so that he had a complete circuit of rarefied air. No inductive effect of any kind was observed, even when the calculated E.M.F. was upwards of 5,000 volts, a result which seemed to show that in an ordinary vacuum tube the current passes entirely by convection. But a later experiment, also due to M. FOEPPL, casts some doubt upon

Digitized by Google

this conclusion. He finds that when an exhausted tube (without electrodes) is placed within a solenoid through which *a Leyden jar is discharged*, luminous phenomena are seen to take place in the tube. It would be important to know whether this effect occurs both with oscillatory and non-oscillatory discharges.

Since Dr. Oliver Lodge made his remarkable discovery of the influence of the static discharge upon the dissipation of vapour, it has often been suggested that experiments should be made upon a large scale to see whether by this means a fog could be locally alleviated—or may we say—dislodged. The atmospheric conditions now existing in London are of the most favourable character, and our own experience would suggest that the neighbourhood of Fleet-street offers the best attainable conditions for an *experimentum crucis*. The *Liverpool Mercury* thinks that the experiment would be worth trying on the River Mersey "at any expense," and that, if successful, "the saving of life and property would be enormous." It also suggests that "the best way to try it would be to have a large balloon sent up some foggy day, and having it connected with a dynamo." If we may presume to offer an opinion of our own, we think a better way would be to get a good sized Wimshurst machine, mount it under shelter on the roof of a factory, or other building (where it could be geared on to some convenient shafting), and provide suitable discharging points. The whole thing could probably be done for £10. Why does not the Smoke Abatement Society take it up?

Some fresh experiments are reported from New York in connection with the electrical execution business. As the proceedings took place in the presence of Mr. Gerry, who is described as "the author of the law enacting that the death penalty shall in future be inflicted by electricity," we were at first led to believe that some welcome misgivings had crept over the New York authorities, and that they were opening their minds to sense and decency. But a quite other complexion is put on the incident when we learn that the tests were applied at Mr. Edison's laboratory, and by Mr. Harold P. Brown. Needless to say the current was an alternating one, and was laid on thick enough to kill first a calf and then a horse. The question to be decided, ostensibly, was one of weight, and as the calf was a light weight, and the horse a heavy weight, the current killing both with equal ease, the demonstration was deemed both comprehensive and decisive. For the real objects of the experimenters probably it was. But on the point at issue—that is to say, the efficiency of capital punishment by electricity—we should like to ask whether the calf and the horse were told what was going to be done to them? We can assure the New York authorities in this relation that there is all the difference in the world between your knowing what to expect and being taken by surprise. We do not doubt the possibility of killing the most hardened criminal by an electrical shock; but criminals, whatever their weight may be, are neither calves nor horses; and not even Mr. Gerry has yet suggested that malefactors should be done to death unawares.

Frankfort.—The Frankfort Offenbach Electric Railway will shortly be lighted along its entire length by arc lamps.

The International Telegraph Convention.—The Argentine Republic has joined the International Telegraph Convention.

The Patents, Designs and Trade Marks Act.—On Monday last the Royal Assent was given to the Patents, Designs and Trade Marks Bill.

Paris.—The Bourse de Commerce at Paris will shortly be lighted by 2,500 incandescent lamps. The dynamos supplying the current will be driven by compressed air.

Berlin.—The Berlin Municipal Council has decided not to accept the offer of the "Thuringer Bergbau Gesellschaft" to light the Muhlenstrasse by means of Brush lamps.

Ilfracombe.—The Ilfracombe Local Board has received three tenders for lighting the town by gas, electricity, and oil, and has "laid them on the table." The tender for the electric light mounts up to £1,500.

Threshing Corn by Electricity.—At the Giant's Causeway Mr. Traill is using an electric motor for threshing purposes, and recently a large stack of oats was passed through a threshing machine of the ordinary construction in about two hours.

The Electric Resistance of Cobalt in the Magnetic Field.—S. Joé *(Il Nuovo Cuinento)* finds that the electric resistance of cobalt in the magnetic field is *increased* in the direction of the lines of force, and *diminished* in the plane at right angles.

A New Electro-Technical Society.—A new electro-technical society, called the "Centro Technico dos Electricistas Brazileiros," has just been founded at Rio de Janeiro. The temporary address of this society is Arsenal de Marine, Rio de Janeiro.

Electricity in the Navy.—Mr. Lane, who has had charge of the electrical shops at Portsmouth without any distinctive position for a great number of years, has been appointed by the Admiralty to the new office of "electrician of the dockyard," with a substantial increase in pay.

Woolwich Arsenal.—We understand that Messrs. Drake and Gorham's tender for the lighting of the new central offices at Woolwich has been accepted, and although the building is to be ready for occupation early in January, the contractors foresee no difficulty in starting up the installation by the time required.

The Alkaline Accumulator.—Mr. P. Bedford Elwell writes us from Deauville to the effect that the statements which have been made with regard to the new alkaline secondary battery used by the French Government, and with which his name is connected, are incorrect in some respects, and were not made on his authority.

Royal Institution.—Prof. Dewar will deliver a series of afternoon lectures at the Royal Institution during this week and next, entitled "Clouds and Cloudland." These lectures, which are intended for a juvenile auditory, will take place on Saturday, December 29th, Tuesday, January 1st, Thursday, January 3rd, and Saturday, January 5th, at 3 o'clock.

Bradford.—At the Bradford Town Council Alderman F. Priestman, in moving the adoption of the proceedings of the Gas Supply Committee, explained that owing to a fire at the works of the contractor for the engines (Messrs. Willans and Robinson) the electric light would not be installed before the end of March. A number of persons had already signed agreements to take a supply of electricity for three years.

The Electric Light in the Field.—Some interesting experiments were recently made on Hampstead Heath by the members of the Medical Staff Corps, for the purpose of testing the capacity of small electric hand-lamps in searching for wounded men left after a battle. The results achieved indicate sufficiently well that the electric light thus used would be of great value, and tend to reduce the suffering of men left upon the field at the close of a fight.

St. Ouen.—The Société pour la Transmission de la Force has just commenced work on a central lighting station at St. Ouen, near Paris. The buildings will be large enough to receive engine power amounting to 500 horse-power. The current will at first only be supplied to St. Denis and Asnières, but later on

Digitized by Google

the mains will be extended to Levallois. Asnières will have several subsidiary stations, where the current will be transformed and distributed to the consumers.

Telegraphic Communication with the Continent.—It is understood, says the *Daily News*, that a contract was signed between the Treasury and the Submarine Telegraph Company last week, prolonging the agreement at present existing, by which all messages from France, Belgium, and Germany pass through the hands of the Submarine Telegraph Company, until March 31st, 1889. The agreement would otherwise have expired on December 31st.

The Cardew Patents.—We understand that Messrs. Drake and Gorham have purchased the whole of the electrical patents held by Captain Cardew, R.E., the only exception being his measuring instrument in America. These patents include not only the well-known Cardew voltmeter but other devices in connection with central station lighting. They are proposing not to manufacture the apparatus themselves, but to license a few firms of good standing to make under royalty.

Central Station Lighting in Austria.—Our Vienna correspondent informs us that a new electric light company is to be started by the Union Bank, in conjunction with Messrs. Ganz and Co., of Budapest. This enterprising firm is doing so much work in all their various branches of manufacture that they evidently have almost more to do than they can get through. The new company intends to make central station lighting its speciality. The proposed capital is 2,000,000 florins (£200,000).

Taff Vale Railway and the Electric Light.—The directors of the Taff Vale Railway have decided to carry out the suggestion of their engineer (Mr. H. O. Fisher) to light two Penarth trains by electricity. The experiment will be tried for six months to commence with, and it is expected that the light will be ready early in the new year. The work has been entrusted to Messrs. J. B. Saunders and Co., electrical engineers, of Cardiff, who are the local agents for the Railway Electrical Contractors (Limited), of London.

Electric Launches.—The "Viscountess Bury" was launched last week from Platt's Eyot, Hampton. This boat measures 65ft. in length, with a beam of 10ft., and a mean draught of 22in., and has a displacement of 12 tons. The "Viscountess Bury" is constructed to carry about eighty passengers, and is propelled by twin screws, driven from two Immisch motors of 7½ horse-power, each of which takes current from 200 accumulators. The recharging is to be effected at any one of Messrs. Immisch's charging stations, which are in course of construction at several points on the River Thames.

Electricity in Honolulu.—The two telephone companies in Honolulu have 1,000 subscribers among a population of 2,000 souls. The Mutual Telephone Company have erected telephone posts upon the reefs in the bay to allow vessels to communicate with the shore. The subscription is only from 24 to 36 dollars per annum, and yet the companies make a good profit. The electric lighting is undertaken by the Thomson-Houston Company. The station is three miles outside the town, and is run by water-power; 60 arcs and 400 incandescents are supplied. The lighting is under Government control.

St. James's Vestry.—At a meeting of this Vestry on Thursday last week the Lighting Committee recommended that the application on behalf of the House-to-House Electric Light Supply Company for consent to apply to the Board of Trade for a license to supply electricity within the parish be opposed, on the ground that there were already enough companies in the field, and that the Board of Trade be requested not to grant a provisional order to the Westminster Electric Light Supply Corporation on the same grounds. On the motion of Mr. William Jenkins, the foregoing recommendations were agreed to.

Chelsea Vestry.—At a meeting of this Vestry last week the Hon. Conrad Dillon presented a petition from over 420 householders in the north-eastern portion of the parish on the subject of overhead wires. He said the petition was signed by persons in all the streets of the north-eastern portion of the parish. The overhead wires were a great nuisance, and should be put underground. The Vestry had taken great pains to tie down the Chelsea Electricity Company under stringent regulations to lay their lines underground, and he thought other companies should be also brought under control. He begged to move that the petition be referred to the Electric Light Committee.—After some discussion the motion was agreed to.

Belgian Commission for Applications of Electricity in the Interior of Coal Mines.—We learn that a Royal Commission of mining inspectors has lately been instituted in Belgium for studying the conditions of security to be provided in the applications of electricity underground in the workings of collieries (particularly in fiery mines) for firing, for fixed and portable lighting, and for transmitting motive power. The President of this Commission is Mr. Roberti, principal inspector, Brussels; and the members are the following inspectors:—Mr. A. Macquet, of Mons; Mr. J. Libert, of Liége, and Mr. E. Masson, of Charleroi, secretary, all of whom are electrical engineers. The first meeting took place on Monday last.

Edison Patents in Canada.—An action is being brought by the Royal Electric Company of Boston, in the Ottawa Courts, for the invalidation of the Edison patents for incandescent electric lighting in Canada, held at present by the Edison Electric Light Company of Montreal. Associated with the petitioners are the Westinghouse Company and the United States Electric Lighting Company, of Pittsburg, Pa. The cancellation of the patents is sought on the ground that Edison failed to comply with the Canadian patent regulations, which provide for the manufacture of the article in Canada two years after the patent is awarded. A large number of expert witnesses will give testimony. The Bell telephone patents in Canada were cancelled a few years ago for the same reason.

The City and Guilds Technical College, Finsbury.—The "special" courses announced to begin at the City and Guilds Technical College, Finsbury, in the new year include a set of lectures by Prof. Perry on "The Application of the Differential Calculus to the Practical Problems of Electrical and Mechanical Engineering," and a course of laboratory instruction in electro-deposition by Mr. Rousseau. The "ordinary" courses of electrical instruction at the Finsbury College are continued as usual. Prof. Thompson lectures on Wednesday on "Magnetism, Electro-Magnetism, Primary Batteries, and Galvanometers," and on Mondays on "Electric Lamps (arc and incandescent), Dynamos, and Motors." The electrical laboratories are so full that none can be admitted except those who either are engaged in the electric industries, or else have attended a preparatory course at one of the local polytechnics or science schools.

The Electric Light at Cannock Chase Collieries.—At the bi-monthly meeting of the South Staffordshire and East Worcestershire Institute of Mining Engineers, held at the Mason College, Birmingham, Mr. Arthur Sopwith, M.I.C.E., read a paper on "Electric Lighting at Cannock Chase Collieries." He described the system and exhibited lamps and copper cables used in lighting the collieries. He compared the cost of electric lighting with gas in favour of the former. The cables were protected by being enclosed in rough boxes, which were packed with coal-dust and tar. The shops, village church, schools and houses were lit, and there were eighty lights in No. 3 pit. A long and interesting discussion followed, and the president spoke of the Paper as a most excellent one, free from too much science, and laying before the meeting a positive and valuable accomplished fact. A hearty vote of thanks was given to Mr. Sopwith, and it was agreed to have the Paper printed for further discussion.

Bath.—At a meeting of the Urban Sanitary Authority on Tuesday, the 18th, Alderman Gibbs moved the adoption of a report from the Surveying Committee recommending that the seal of the Authority be affixed to a contract with Mr. Massingham for the electric lighting of a part of the district therein named. The contract, he said, was binding on any company to whom Mr. Massingham might entrust its performance. He could not say that he thought that the result attained would give universal satisfaction. He would have been very glad if they could have dispensed with those posts, which would be unsightly, and those overhead wires, which would also be unsightly, if not dangerous. He only hoped that the progress of

Digitized by Google

science might enable them to get the wires underground.—Mr. Heywood wished the committee had seen their way to spend £240 and put the wires underground.—Alderman Brickmann objected to the overhead wires and to the whole of the city having to pay for the light when only one area would profit by it.—The report was then adopted, Alderman Brickmann alone dissenting.

Electric Tramways for Ballarat East.—At a meeting of the Town Council of Ballarat East, Australia, the offer submitted by Booth, Ellson and Co., of Queen-street, Melbourne, on behalf of the Australasian Electric Tramways Company, for the privilege of constructing tramways in Ballarat East, was considered. The following are some of the clauses of the tender, with the Council's recommendation thereon:—Company offer £500 per year for 30 years for sole right to use roads, &c., in Ballarat East, for tramways for 30 years, and quarter of the profits exceeding, or 10 per cent. divided.—Adopted. £250 to be paid before breaking road, £250 within 12 months, and £250 to be paid every six months. Systems—Overhead conductor, underground conductor or storage cells. Adopted.—Cars to be similar pattern to those on Melbourne lines; to seat 16 persons inside and six persons to stand on platform at end of cars. Adopted.—Whole of permanent way reverts to Council at end of 30 years. Provisions for Council to purchase prior to that term on payment of amount of paid-up capital, with interest for remaining term at 10 per cent.; or to purchase at end of 30 years at a valuation. Adopted.—The town clerk was empowered to apply to the Governor in Council for necessary power to delegate construction.

Submarine Telegraph Extensions.—Interruptions of telegraphic communication with Australia, owing to volcanic eruptions and other causes, have induced the Eastern Extension Telegraph Company to lay a third cable from Banjoewangie to a point in Western Australia, probably somewhere near Beagle Bay. The length of the new cable will be over 1,000 miles. The Telegraph Construction Company are working night and day loading this cable into their ship, the "Seine," which is to leave the Thames on Wednesday next to lay the cable. Mr. C. Riddle is the engineer in charge, and Mr. Thomas Clark is the electrician in chief. The Eastern Extension Company believe that when this cable is laid the chances of any breakdown in telegraphic communication with Australia will be very remote.—Another great cable of 700 miles is now being made by the Silvertown Company, for connecting Loando with Mossamedes, on the West Coast of Africa; while the Telegraph Construction Company are making a cable of 1,500 miles to connect Mossamedes with Cape Town. This work will be completed in March next, and thus there will be two telegrapic routes to South Africa, one *vid* the East and the other *vid* the West Coast—an important boon in the event of any grave crisis again arising in that quarter of the world.

Resistance of Alloys.—C. L. Weber, in Wiedemann's *Annalen*, XXXIV., 1888, gives the results of some experiments on the resistances of alloys of tin and lead, and tin and bismuth, at high temperatures. Pure tin on melting exhibits a sudden increase of resistance, and a similar phenomenon occurs with an alloy corresponding to the formula Pb_2Sn_7. In the case of other alloys the increase of resistance may be classed under two heads; first, in the case of all alloys there is a rise at (the first melting point) about 180°C., and a further rapid increase of resistance until the fusion is complete; the former rise is the more marked the simpler the formula of the alloy. The alteration in resistance in all cases is somewhere about 50 per cent. For tin-bismuth alloys the case is different; these have all an approximately constant melting point, about 140°C., but differ in their other properties. In the case of alloys containing only up to 12 per cent. of bismuth the melting point is not very noticeable, though apparently a little lower than pure tin; from 25 to 50 per cent. bismuth alloys the resistance suddenly decreases, and then begins again to increase at 60 to 80 per cent. Bismuth shows a steady decrease of resistance during the whole period of melting; the smallest change noticed was in the case of a 54·5 per cent. bismuth alloy, but Herr Weber considers it probable that an alloy between 55 and 60 of bismuth corresponding to the formula Bi_3Sn_4 would have a still smaller alteration in resistance. Temperature coefficients lie between 0·2 to 0·4 per cent., and 0·05 to 0·08 per cent., for the alloys in the solid and liquid state respectively. Herr Weber concludes from his experiments that the decrease in resistance of bismuth, when melted, is due to an essential property of the metal, and not to an accident of structure.

St. George's Vestry.—On Thursday, the 20th inst., the Electric Lighting Committee recommended that an application from the London Electric Supply Corporation to light with electricity the area between Hamilton-place and St. George's Hospital, as far down Grosvenor-place as Halkin-street, be granted upon an agreement being entered into embodying the following conditions, viz.:—That the corporation bear the whole expense of the laying of wires, &c., for making the experiment, and that a light quite as good as that now given by gas be supplied to the satisfaction of the Vestry, who will pay £300 per annum for the lighting of the area, the agreement to be for a period of twelve months certain, after which it should continue unless determined by three months' notice on either side. That the corporation reinstate the parish lamps and paving, if removed or interfered with, to their present condition, and that no use of the parish lamps by the corporation shall in any way interfere with their being lighted by gas, at any time, if so required, and the details as to the exact system of lighting be left to the corporation. The Electric Lighting Committee recommended "That the Vestry resolve that it is in their opinion to the advantage of this parish, and, so far as the Vestry could see, of the inhabitants of London generally, that joint-stock companies should commence operations for electric lighting under licenses rather than provisional orders."—Lord Hobhouse, in moving the adoption of this report, said the company had already wires laid within this area. The expense of lighting the area by gas was about £300, and so they had fixed that sum in the agreement.—Mr. Southon seconded the motion, which was agreed to, with a rider prepared by Sir Walter Phillimore, regretting that the Board of Trade had refused to enter into the proposal of granting licenses on a principle which would seem to prevent any licenses in future being granted to them.

Frictionless Bearings.—An ingenious improvement in the manufacture of frictionless bearings has been invented by Mr. Frank Garrett, M.I.C.E., of Leiston Works, Suffolk, and is being introduced by the firm of which he is the principal. These bearings are made of Babbitt's metal, or some other similar alloy, and they are cast in solid metal chills, which are worked up with the greatest accuracy, so as to produce externally of the bearing the exact outline of the interior of the plummer block, whilst the interior of the bearing corresponds mathematically with the journal which it is intended to support. The chills are, moreover, so designed that the bearings would form a complete circle but for the intervention of a dividing plate, which separates the metal and forms two castings, each complete in itself, and together forming a perfect circle. The cast-iron plummer blocks are also so constructed as to present uniform interiors for the reception of the bearings. The chief merit of this system (says *Iron*) consists in the absence of the friction caused in all gunmetal bearings, which have been bored or machined, however carefully, in consequence of the exposure of the rough edges of the minute particles which form the surface of the bearing, and which catch against microscopic projections on the surface of the journal. In Mr. Garrett's bearings no boring or machining takes place, the metal being cast in chills. The bearing surface is consequently composed of unbroken molecules of metal, and since these molecules do not possess individual strength to resist the friction of the journal, they are flattened to a perfect polish, and a great economy of power and lubricant results. It has long been usual to bush metal bearings by pouring Babbitt's metal in a molten condition into the cavity existing between a journal and its bearing, the latter being purposely bored out larger than the journal for this purpose; but it has remained for Mr. Garrett to produce accurately-finished and interchangeable bearings of this material, such as can be readily replaced by others of mathematical identity when replacement becomes necessary. This system was exhibited on Messrs. Garrett's stand at the Smithfield Club Show.

NOTES ON ELECTRO-MAGNETIC INDUCTION.

BY DR. J. A. FLEMING, M.A.

(Continued from page 161.)

An elaborate investigation into the duration of induced currents was made by Blaserna.*

A commutator was constructed which consisted of two insulating cylinders keyed on one shaft and having on part of their surface brass coverings cut into steps (*see* Fig. 15). These cylinders were capable of being set in any relative position to each other on the shaft. The shaft could be revolved at a high rate of speed, and its velocity ascertained by a siren plate attached to the axis. This siren plate consisted of a disc pierced with holes against which was directed a jet of air. From the pitch of the musical note given out, when ascertained by comparison with standard tuning forks, the speed could be determined. Two springs pressed against the hubs of these cylinders and two against the surfaces of these cylinders, and a current entering by the hub was conducted to the brass coating and escaped by the other spring, if the cylinder was in such a position that this last spring was pressing on the metal part. The apparatus, therefore, formed a device by which each pair of springs might be brought into electrical contact for a definite portion of the time of a revolution of the cylinders and be insulated also for a given time, each pair of springs being in connection relatively to the other in a determined manner for a determined time. In the circuit of the one cylinder and pair of springs *m* M was placed a battery, primary coil, and tangent galvanometer, and in the circuit of the other pair a secondary coil and sensitive galvanometer. This being prepared, the primary coil P and the secondary S were placed a given distance apart. On revolving the commutator it periodically interrupts the primary current, the time during which the primary current is kept on depending upon the position of the spring M on its cylinder. The other cylinder can be so set as to collect either the direct or inverse secondary currents, and send them in series through the sensitive galvanometer, the time during which this secondary circuit is closed being capable of regulation by the adjustment of the spring M_1. In his experiments Blaserna first investi-

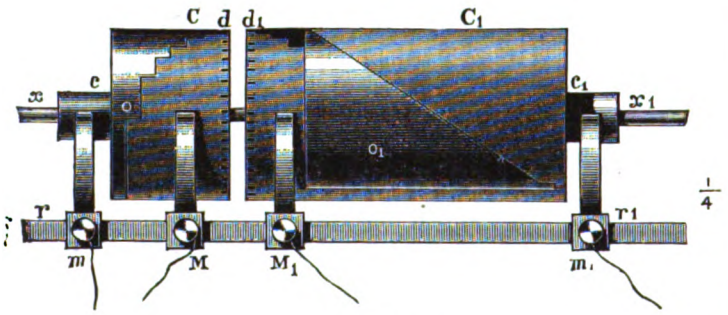

FIG. 15.

gated the duration of each of the induced currents. The interrupters were so arranged relatively to one another that whilst the primary circuit was made and broken, the secondary circuit was not closed until a small time after "making" the primary, and then broken again before the primary was broken. By adjusting the secondary interrupter a position could be found in which the galvanometer just showed no current. The interval between the closing of the primary and the opening of the secondary was then the interval occupied by the secondary current, and this was the duration of the "make"-induced current. Blaserna found that the "make" secondary (inverse) lasts a longer time than the "break" current (direct). For the coils used the times were—

Inverse secondary lasts ·000485 second.
Direct secondary lasts ·000275 second.

He next proceeded to obtain the curve of each current, and to determine the time of arrival at a maximum.

* Blaserna, *Sul sviluppo e la durata delle Correnti d'induzione*, Giornale di Science Naturali, Vol. VI. (Palermo, 1870).

The secondary interrupter was so set that the secondary circuit was closed just before the primary, and opened after at a certain definite interval of time. The galvanometer thus received a current which was made up of repeated doses of the whole quantity of the induced current up to a certain fraction. Knowing the speed of the commutator and the coefficient of the galvanometer, the value of the whole quantity of the induced current, extending over a certain fraction of its whole duration, was known; and from those observations, repeated at regular progressive intervals during the whole period of the current, the value of the ordinates of the current curve can be obtained. For if the curve (Fig. 16) A P P′ B (upper figure) represents the variation of current during a time A B, so that P X = y represents the current strength at a time X and P′ X′ represents the current strength after a very small interval of time X X′ = $d\,t$. Then the area P P′ X′ X = $y\,d\,t$ represents the quantity of electricity which has passed in the time X X′. Call this d Q. Hence $d\,Q = y\,d\,t$, or $y = \frac{d\,Q}{d\,t}$.

Suppose another curve A′ P′ R (lower curve) is drawn on an equal abscissa A′ B′, such that its ordinate at every point represents the whole area of the upper curve up to the corresponding point—that is to say, the lower curve is a curve such that its ordinate P′ X′ is proportional to the area A P X of the upper curve, A X (upper curve) being equal to A′ X′ (lower curve) when the time interval $d\,t$ becomes very small. It is easily seen that if the area A P X (upper curve) is called Q, and the ordinate P X is called y, that the tangent of the angle P′ Y X′ (lower curve), which the geometrical tangent drawn at P′ makes with the axis A′ B′, and which is represented by $\frac{d\,Q}{d\,t}$, is proportional to the ordinate P X. Hence the upper curve is a derived curve of

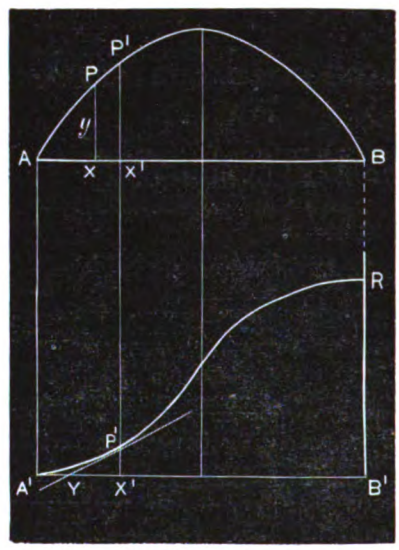

FIG. 16.

the lower, and if we are given a curve like the lower curve, the ordinates of which represent the whole quantity of electricity which has from a given epoch flowed past a point, we can, by drawing a curve whose ordinates represent the *slope* of the first curve, obtain a second curve, which is a curve of current. In this way it is possible to describe the current curve, and to determine its form and position of maximum.

Blaserna found that the greater the distance apart of the primary and secondary—in other words, the less the mutual inductance—the less was the maximum value of the secondary current, and the greater the delay in the appearance of that maximum. This is in accordance with theory. In the case of the "break," or direct secondary current, he found the delay in establishing the maximum not so great, and the maximum ordinate was greater, though the total duration of the current less. He established by direct experiment the equality of the quantity of the two induced currents. When the coils were very near together the induced current at starting established itself by a series of *electrical oscillations*.

(To be continued.)

DYNAMO REGULATION BY MEANS OF A THIRD BRUSH.*

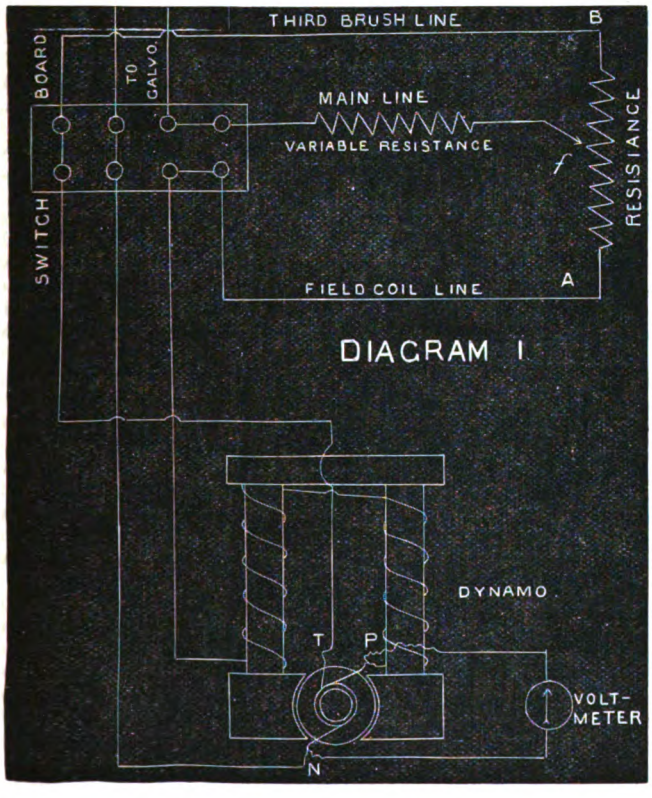
BY EDWARD CALDWELL, A.B., M.E.

The following study of methods of third brush regulations of series dynamos for *constant current*, was taken up at the suggestion of Prof. Nichols. During the progress of the experimental work it was discovered that a similar method of regulation might be applied to a series-wound dynamo for the production of a *constant electromotive force*. The investigation was made to include, therefore, the applicability of this method of regulation to a series-wound dynamo, both for a constant current and a constant electromotive force.

The dynamo used in this work was a small series-wound machine, with two upright field magnets of the Edison type and a Gramme armature. The cores and yoke were of the best Norway iron. The principal dimensions and constants of the machine were as follows :—

Diameter of armature, outside	$4\frac{3}{4}$ inches.
Length „ „ „	$2\frac{1}{4}$ „
No. „ „ coils	30
Resistance „ through brushes	·72 ohm.
Diameter of field-magnet cores	$2\frac{3}{8}$ inches.
Length of field-magnet cores	$7\frac{3}{8}$ „
Size of yoke	2in. by $2\frac{3}{8}$in. by $10\frac{1}{4}$in.
Turns of wire on each field coil	785
Resistance of each field coil	·8 ohm.

A third brush, held by an independent brush holder, was placed upon the commutator between the regular brushes. This could be set at any desired angle in advance of the positive brush, a pointer indicating the angle upon the graduated circumference of a wooden ring placed concentrically with the shaft. Another pointer indicated in a similar manner the angular lead of the regular brushes.



Each of these pointers was set at zero of the graduated scale when the brush which carried it rested at the upper end of the vertical diameter of the commutator—a point midway between the edges of the pole-pieces.

The field was explored for distribution of potential around the commutator by a modifiation of a method described by Prof. Brackett, in a Paper read before the American Institute of Electrical Engineers in 1884, and published in Vol. I. of the *Transactions*.

The current was measured by a tangent galvanometer, the coil being formed of a single ring of copper, 50 centimetres in diameter, and of rectangular cross-section. Its constant was determined by comparison with the large standard tangent galvanometer, in the magnetic observatory of Cornell University. The deflections could easily be read to tenths of a degree.

The E.M.F. was measured by an Ayrton and Perry voltmeter, which had previously been calibrated. The voltmeter was shunted across the regular brushes of the machine.

* Revised abstract of graduating thesis, Sibley College, Cornell University, June, 1888. Reprinted from the New York *Electrical Engineer*.

Digitized by Google

The resistances used in the external circuits were made of German silver wire coiled in the form of a spring, and stretched upon upright wooden frames. By means of a copper hook contact could be made at any desired point. These coils were standardised by comparison with the coils of an Elliot Brothers resistance box of the dial pattern.

The arrangement of the apparatus during the first portion of this investigation differed from that of the Waterhouse Electric Company in their system of third brush regulation for constant current* only in that the point of contact of the main line with the resistance coils of the regulator was varied by hand instead of by automatic means.

The connections used are shown in Diagram 1. The switchboard contained eight small mercury cups—two each for the terminals of the galvanometer, the third brush line, and the main line, and was so arranged that the galvanometer could be placed in any one of the three circuits.

The machine was first run at 2,500 revolutions as an ordinary series machine with two brushes, these being adjusted to the non-sparking position with a lead of about 12 degrees. Table 1 gives the data obtained from which the characteristic curve in Plate A is plotted.

TABLE 1.

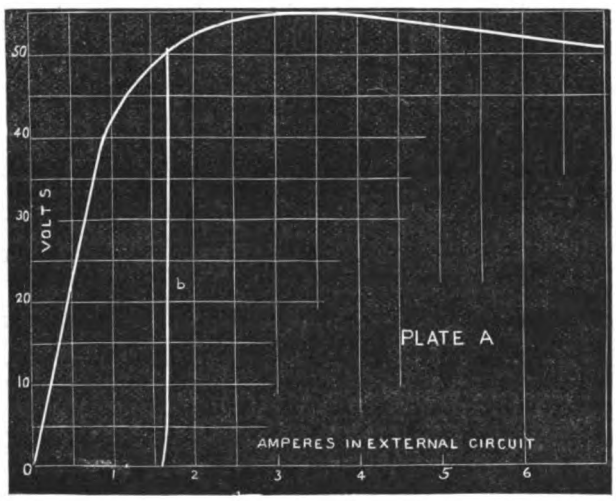
54	2·35		

It will be noticed here that a very small amount of current is sufficient to saturate the field-magnets because of the very large number of turns of wire on the field-coils.



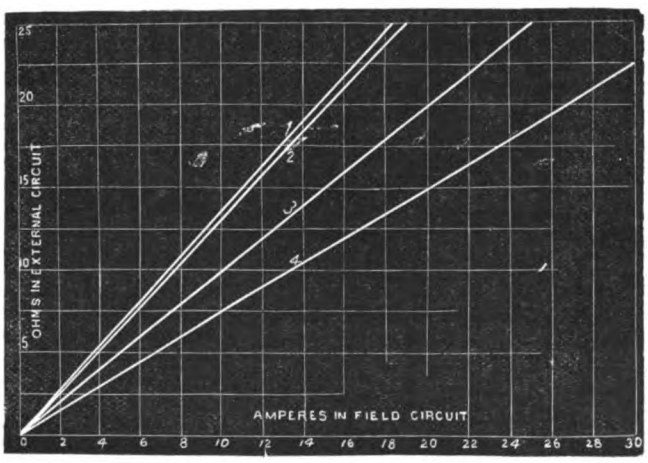


PLATE 1.

With the third brush upon the commutator a study was made of the effect of increasing the angular distance between the third and positive brushes. The tabulated results are given in Tables 2 to 6. The third brush remained fixed through each set of observations, and the main brushes, at a lead of 12°, through all the five sets. The resistance between the third and positive brushes was 21 ohms.

The curves of relation of E.M.F. and current, of which curve *b*, Plate A, is an example, need not be plotted, as an inspection of the tables will show that within the limits of regulation the curves are superposed vertical lines, if the volts be taken as ordinates and the amperes as abscissæ. Curves 1 to 4, Plate 1, are plotted from Tables 2 to 5.

These curves are straight lines, and they show that the condition necessary to constancy of current in a series dynamo, namely, direct proportionality of external resistance and current in the field coils, has been secured. They also show that the greater the lead given to the third brush, the greater the field current necessary to keep the external current constant, the external resistance being the same. This will also be seen by a comparison of columns 3 and 7 in Tables 7 to 10. These tables are compiled from Tables 2 to 6.

But the most interesting as well as the most important phenomenon, shown by all these tables alike, is the change of sign of the current in the third brush line. Under some conditions the third brush acts as a positive brush, and under others as a negative.

Tables 2 to 6 show (1) that with each position of the third brush, on increasing the external resistance, the current in the third brush circuit at first decreases, becomes zero, and again increases in the opposite direction; and (2) that the further the third brush is in advance of the positive the higher is the current in the third brush line at first, the sooner the zero point is reached, and the higher the current rises in the opposite direction.

Tables 7 to 10 show (1) that with advance of the third brush, the external current and resistance being kept constant, the E.M.F. continues to rise while the current in the third brush line gradually decreases, passes through zero, and again increases in a negative direction; (2) that this zero point is also the point of maximum additional resistance in the field, and of minimum additional resistance in the third brush line; and (3) that this zero point is reached sooner the higher the external resistance.

It was at first thought that these changes might be due to a distortion of the neutral line of the armature, since with each change in external resistance there was a corresponding change of strength of field, while the current flowing up through the armature from the negative brush remained constant. An exploration of the field, however, by the method alluded to, showed that under extreme variations of current in the field, the neutral line did not change position as much as 10 degrees, an amount quite insufficient to account for the changes shown in the tables.

It will be noticed that the application of the third brush destroys the symmetrical flow of current in the armature. If the third brush be positive it will take off a part of the current flowing up on that side of the armature, and the coils lying between the third and positive brushes will have less current than the other coils. But if the third brush be a negative, the current returning to the armature by the third brush line will be added to the coils lying between the third brush and the positive. Neither will the current flowing up on one side of the armature be equal to that on the opposite side, since the resistances of the two paths offered to the current are not equal. The result of this unequal distribution will be, in extreme cases, to throw the neutral points of the armature off the ends of a diameter and on that side of a diameter where the coils are traversed by the weaker current. If, however, as was the case with the machine used in this investigation, the magnetic moment of the field is very great as compared with that of the armature, this effect is inappreciable.

But these variations of current in the third brush line may be satisfactorily explained without reference to the distortion of the diameter of commutation. It is a well-known fact that the total E.M.F. generated in the armature coils increases around the commutator from the negative brush to the positive, each coil adding its share to that induced in the coils preceding, and that the E.M.F. again falls, through the same range, from the positive brush around the external circuit to the negative brush.

Let E_d be the drop of potential between the positive brush and the point at which the third brush line joins the main circuit, and let E_i be the rise of potential between the third and positive brushes—that is, the E.M.F. induced in the coils which lie between these brushes.

It is evident that if $E_d = E_i$, no current will flow in the third brush line, its two ends being at exactly the same potential. But if $E_d > E_i$, the third brush will be at a point of higher potential than the other end of the third brush line, and current will flow *out of* the armature through the third brush. If $E_d < E_i$, the reverse effect will be produced, and current will flow along the third brush line *into* the armature.

Now $E_d = C' R'$, where C' and R' are respectively the current and resistance of that part of the circuit between the positive brush and the junction of the third brush line with the main line. Also,

$$E_i = \frac{2}{\pi} w H' A' = 4 n H' A'.$$

* See *Electrician*, October 12, p. 738.

Digitized by Google

A′ being the "equivalent area" of the coils lying between the third and positive brushes; H′, the strength of the field; w, the angular velocity; and n, the number of revolutions per second of the armature.

There will be equilibrium between the ends of the third brush line when $E_d = E_i$, that is, when

$$C' R' = 4 n H' A'.$$

The speed remaining constant, this equation shows that any one of three changes will make $E_d > E_i$, and so make the third brush positive.

(1) *Increase of* R′.

This will occur if the finger *f*, Diagram I., be moved towards the point B. This change will produce a corresponding decrease of C′ and H′, but below the saturation point these practically vary in direct proportion, and will not change the value of the equation.

(2) *Decrease of* A′.

This may be done by bringing the third and positive brushes nearer to each other, thus decreasing the number of coils between them.

(3) *Increase of* C′, the field-magnets being saturated.

If H′ remain practically constant because of the saturation of the iron, an increase of C′, caused by a decrease of the resistance of the external circuit, will make $E_d > E_i$.

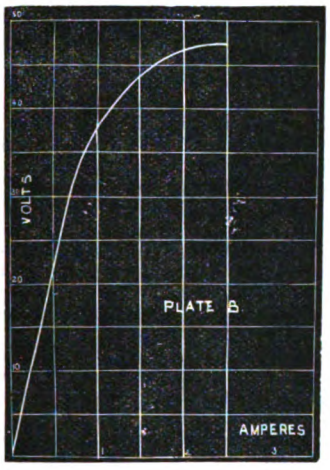
The three opposite changes will make $E_d < E_i$, viz. :—

(1) *Decrease of* R′.

(2) *Increase of* A′.

(3) *Decrease of* C′, the field-magnets being saturated so that H remains constant.

A change of speed, n, would produce a complex change of all the factors except A′. All of the variations of current in the third brush line may be traced to one or more of these causes.



It will be noticed that the difference of potential between the main brushes is always the same—between 50 and 51 volts—when the current in the third brush line changes sign. This is the point at which the new characteristic crosses the characteristic of the regular series machine, as shown in Plate A, where the characteristic curves from Tables 1 and 2 are plotted together. When the third brush is positive it robs the field coils of a part of their current and adds this to the main-line current, and when it is negative it diverts a portion of the current from the main line, adding it to the field-circuit line.

It will also be noticed that curves plotted between field current and E.M.F. from Tables 2 to 6 coincide with the characteristic from Table 1. This would necessarily be so, since in Table 1 the external current is also the field current.

No higher E.M.F. can be reached on the constant-current curve than that obtained from the machine worked as an ordinary series dynamo, the limit being reached as soon as the iron of the field-magnets becomes saturated.

The horizontal distance between corresponding points on the constant current curve and on the curve of E.M.F. with field current, measures the amount of current flowing in the third brush line at that point, and also shows whether it is positive or negative.

It is evident that the point of crossing of the two characteristics —that is, the point at which the current in the third brush line becomes zero, will depend upon the *amount* of the constant current in the external circuit. Tables 11 to 14 give the data obtained when the external current was held respectively at 1·0, 1·5, 2·0 and 2·5 amperes. The points obtained by plotting field-current with E.M.F. fall, as before, upon a common curve, as shown in Plate B, and constant current curves for 1·0, 1·5, 2·0 and 2·5 amperes cross this curve at 38, 44, 47 and 47·5 volts E.M.F. A curve for ·5 of an ampere would cross the characteristic at about 22 volts.

Below the saturation point of the iron the relation between current in the third brush line and E.M.F. is one of direct proportion. When the saturation point is reached current in the third brush circuit may increase indefinitely without increase of E.M.F.

No very large *negative* current is obtained in the third brush line until the third brush is 90deg. or more in advance of the positive. This would seem to indicate that the constant-current characteristic cannot be carried much, if any, above the regular-series characteristic unless the third brush has a very large lead, and this is objectionable because of very bad sparking at the third brush.

This arrangement is in reality equivalent to a compound-wound dynamo in which one set of field coils is made to carry the current for both the series and shunt coils of the usual type of compound-wound machine. Referring to Diagram I, and the last line of Table 4, it is clear that the field coils act as *series* coils in carrying a current of 1·70 ampere from P, the positive brush, around the external circuit to the negative brush N, and that at the same time they act as *shunt* coils in carrying ·65 of an ampere from P, around the field-magnets and back to T, the third brush. There is, however, this further distinction to be made between this arrangement and the usual type of compound dynamo—that that part of the field current which partakes of the character of a shunt becomes zero under certain conditions of the external circuit, and that beyond this point the shunt circuit acts as a differential coil wound upon the field-magnets. This is effected, not by an opposing current being sent around the field, but by the shunt becoming a *shunt around the series field coils*, thus depriving them of a part of the current they would otherwise receive, and so weakening the field. This is shown by the first line of Table 4, where, of the 1·70 ampere in the external circuit the field coils carry but ·35, while a current of 1·35 ampere is shunted around the field by the third brush line and added to the current in the main circuit. Though common enough in motors, the writer is not aware of any other case in which a differential coil or anything analogous to it is applied to a generator.

The arrangement then embodies at once the principles of three distinct types of dynamos, the type used being determined solely by the resistance of the circuit if the external current be kept constant. In keeping a constant external current, however, the resistance of the series field changes.

These three types are :—

1. Series dynamo + differential shunt coils (or rather what has the same effect as differential shunt coils).

This type is brought into use when the third brush is at a higher potential than the junction of the third brush line with the main line and a portion of the total current of the armature is diverted from the field coils, decreasing the strength of the field.

2. Plain series dynamo.

This is the type made use of when both ends of the third brush line are at the same potential and the current flowing in it is *nil*, which occurs at the point of intersection of the two characteristics.

3. Series dynamo + cumulative shunt coils.

This occurs when the junction of the third brush line with the main line is at a higher potential than the third brush and current flows into the armature at the third brush.

It should be noticed that in this combination the total resistance of what corresponds to the shunt-circuit of the field, including the resistance of the field coils and whatever resistance may be placed between the third brush line and the field line, is a constant, while the resistance of what corresponds to the series circuit of the field is variable, being changed by the movement of the finger *f*, Diagram I, along the resistance A B.

(To be continued.)

LEGAL INTELLIGENCE.

Edison and Swan Electric Light Company v. Holland and Others.

TUESDAY, DECEMBER 11.

The ATTORNEY-GENERAL commenced his reply this morning, and stated that he should not condescend to notice various points which had been dealt with by counsel on the other side. He did not go back from anything which he had said before with regard to the importance of this invention of Edison's being the real starting point of the improvement in electric lighting, and he entirely denied that Swan and Stearn were not indebted to Mr. Edison for what they had done. The learned counsel was about to refer to the specifications to prove his position, when

LORD JUSTICE COTTON said that they had stopped Mr. Finlay from going into this, considering that it was better that he should go into the evidence to prove that part of his case

Digitized by Google

The ATTORNEY-GENERAL said that Mr. Finlay was not stopped in his description to the Court on the previous day.

LORD JUSTICE COTTON: I say if there is evidence to show that before a certain time there were difficulties with carbon burners which were afterwards removed by certain processes being adopted, that is legitimate to go into, and it may remove the effect of the great start then made in electric lighting; but we stopped Mr. Finlay from going into the specification and saying, Here is an invention. We do not know that it is an invention by merely putting before us the specification.

The ATTORNEY-GENERAL: I accept the distinction; but I must be allowed to say that if there remain in your lordships' minds any lingering doubts upon the suggestion that the step was taken by these subsequent improvements, not by Edison's enunciation, I claim to show that they are every one identically the same combination, and there is no evidence whatever of any difficulty being removed by the subsequent improvements. There is no evidence whatever beyond the fact that the lamps were cheaper, and that they lasted longer, and that they could be made more quickly, of the later lamps being anything different from Edison's combination; in fact, their strongest witness admits that I am right in that respect. Mr. Finlay has told your lordships that this burst of electric lighting came from something else; but that is a question of evidence. I say that it is as clear to-day as it was in 1880 or 1881 that it was the enunciation of Edison's combination that had made the step, and nothing else. They say that Edison taught Swan nothing. I desire to demonstrate from the evidence that Swan took fairly, and honestly, and readily, Edison's publication of 1879, and used it, and for that purpose I will refer your lordships to the evidence between Mr. Swan and Mr. Stearn in 1879. Mr. Swan had worked that paper carbon 15 or 20 years before, and had abandoned it as hopeless. F J B 1 had no copper and platinum caps, and the thing is put into more concrete shape by Mr. Stearn himself. Mr. Swan had evidently designed something to get the carbon to bend, and in the correspondence between Mr. Swan and Mr. Stearn on the subject of these inventions it was clearly shown that there was something about carbon bending, and that they little appreciated the fact that the carbon conductor could be bent before it was carbonised, and from February, 1879, to February or March of 1880, these two gentlemen never reverted to the vessel wholly of glass. Lord Justice Fry and Lord Justice Bowen had held that the difference in combination and the Edison design was the difference between failure and success. F J B 1 was abandoned as an experiment, believing that they had gone into a wrong path; as far as we can tell, incandescent lighting might still have been undiscovered but for Edison's publication in the month of November, 1879, for everybody knew everything before, and it was known to Swan, and I think with all that knowledge they were going backwards to F J B 1 instead of onwards. I am going to show that this platinum and the same method of carbon conductor continued through to September, 1879, and the departure made by Swan was after he had heard what Edison had done. This attempt to deal with the platinum caps was their method of trying to get rid of the large conductors, which went through the glass and thereby cracked the glass. But there is a more important point in the giving way between the carbon and the contact where the carbon joins the platinum. The learned counsel proceeded to read the correspondence between Messrs. Swan and Stearn, and then went on to say that as to the alleged absolute worthlessness of Edison's discovery he should show that the mode of connecting the thin piece of carbon at the platinum wires is to-day one of the best and most serviceable ways of doing it, and that it is a complete novelty and an absolute departure, and that which is plagiarised and improved in all directions. The difficulty of contact was very great until the appearance of Edison's patent. The hairpin carbon broke down because they did not understand how to attach it, and the correspondence between Mr. Swan and Mr. Stearn shows that they were trying to construct the pencil on blocks, and there was a picture [produced] which has thinned down to a very minute line in the middle, something like a partial thread, and they thought that the only source of danger was removed; but nevertheless they abandoned the experiments. These experiments between Messrs. Swan and Stearn demonstrate the fallacy of Mr. Finlay's position, that Edison taught the world nothing. When this is understood it will be shown that it was Edison's enunciation of that invention that did solve the question of success, and there never has been anything to improve it to this day in the connection of multiple arc lighting except simply an improvement in the manufacture of Edison's patent, making it cheaper, longer lived, and more commercial, and better for public purposes. So far from Mr. Swan asking for an improved conductor, he was trying to see whether or not he could get something to free his carbon from defects which would make the old conductor useless.

LORD JUSTICE BOWEN asked what had been disclosed in the publication of *Nature* in October, 1879.

The ATTORNEY-GENERAL: What Edison had disclosed in *Nature* was the patent for freeing platinum from occluded gases, viz., running upon the pumps. It was described on October 2nd in *Nature* as "The connection of heat in vacuo in metals." Mr. Edison there describes the experiment of electric lighting with platinum, and he then describes running on the pumps with practically the same alteration as in the specification. Swan and Edison were both engaged on the running on the pumps; but Swan was not attacking the improved conductor.

LORD JUSTICE LINDLEY: Stearn said that?

The ATTORNEY-GENERAL: Yes. I mention this because my learned friend's argument is that Mr. Swan in 1879 was working at filamentary conductors, and he now said that Heaviside and Proctor saw these filamentary conductors in 1879. That was a complete mistake on the part of those who instruct my learned friend. The thing they were both working at was running on the pumps. There was no suggestion by Mr. Swan to alter his conductor into a filamentary shape, or anything like it, until he got the description of the thread carbonisation of Edison. Swan never thought of "filament" until February or March, 1880. It is not correct to say that Swan ever put "filament" into his patent in January, 1880. Edison always publishes the substance of his inventions before the complete specification goes in, and in the provisional specification of Mr. Edison, which was in England in the month of June, three months before the time spoken of by the other side, Mr. Edison had actually mentioned carbon as being able to be freed from air by this process. Up to that time Mr. Edison had not developed the filamentary idea. Messrs. Swan and Stearn never attempted to make a thread conductor for six months after this, and it was a little strong for his opponents to say, "Why, Heaviside and Proctor saw these lamps in 1879." Mr. Edison had anticipated Mr. Swan entirely, and Mr. Edison in his provisional specification had described three months before, though it was a secret document until December, what it was alone that had been done by Mr. Swan. The running on the pumps had been secret and experimental, and Stearn said:—"I now show that this had been published, because if Edison has patented it we shall be debarred from running on the pumps." They were completely anticipated. My friend has tried to ridicule and scoff at everything that has been done by Mr. Edison. Up to June, 1879, Edison was working with the platinum filament. The carbon filament was practically only then incubating, it was not developed. On the 3rd November, within seven days of Edison's provisional specification, Mr. Stearn—who is a great expert in the use of Sprengel pumps and Crookes' tubes, from which the air has to be exhausted to a very low vacuum indeed—was referring as to the use of the Sprengel pump, and I used that to show how little Swan and Stearn appreciated the conditions under which they were labouring; so little did they appreciate what could be done that they proposed to let the lamps always stand in water so as to get the heat generated by the current conducted through the water. Is it possible that the greatest experimenter in electric lighting could have gone so far wrong? We shall show that Mr. Swan got his idea, and admits that he got it, from the information he obtained from Edison's patent. I shall show the impossibility of Proctor and Heaviside's evidence, that they saw thread lamps running and burning successfully in Swan's own laboratory and also at Stearn's house.

LORD JUSTICE LINDLEY: I thought you gave that up, Mr. Finlay.

Mr. FINLAY: The difficulty was this, that we could not say that with regard to this there was publication.

The ATTORNEY-GENERAL: But you said so over and over again.

Mr. FINLAY: That was the difficulty, and I thought your lordship was referring to that.

LORD JUSTICE COTTON: I understood you to say that these thread lamps had been used.

Mr. FINLAY: Then I misunderstood your lordship; but I do press it as showing that in the summer of 1879—that is to say before November, 1879—Swan and Stearn were making lamps with this slender carbon conductor. The Attorney-General has used the word "thread" lamp. If my friend by that means a lamp by which the carbon conductor is made of thread, that is based on Swan's evidence. If by that he means that the conductor was slender, like a thread, I say that the effect of the evidence of those witnesses, Heaviside and Proctor, and of Swan and Stearn's cross-examination, is to show that in the summer of 1879 Swan was making lamps with slender threads, which in that sense might be considered thread conductors.

The ATTORNEY-GENERAL: My friend has no right to interrupt because the witnesses say that they saw the lamp, and they described it as a thread lamp, with a loop like the filaments hanging up in the court in which your lordships now sit.

LORD JUSTICE COTTON: It was an attempt to shorten the case, and I got into a difficulty.

Mr. FINLAY: I said with regard to that: I rely upon this as showing that Mr. Swan was making these lamps at that time in substantially the same way with these slender conductors, and I never for a moment abandoned that.

The ATTORNEY-GENERAL: Mr. Finlay heard my opening, when I said I could demonstrate on Swan and Stearn's evidence that nothing of the kind was ever made until March, 1880.

Mr. FINLAY: We rely upon this, that Swan, as shown by Heaviside's evidence, was making lamps with slender conductors, and that is shown by Swan's cross-examination. I ask your lordships to look at the evidence of Heaviside and those other witnesses taken together with the whole evidence of Edison and Swan. The result of that evidence is that Swan really admits practically that he was making lamps with this Carré carbon hair-pin shape before November, 1879. He does not admit it in terms, but the effect of that is so. Then with regard to the filaments made with paper which Heaviside says he saw, I say on Swan's cross-examination in all probability Heaviside is right upon that point, because on the 20th January, 1880, Swan took out a patent for the paper filaments. On the 29th November, 1879, he wrote that letter to *Nature*, which was published on the 2nd January, 1880, which stated that within the last six months he had completely got over the difficulties of the making of carbon conductors from paper.

The ATTORNEY-GENERAL: From running on the pumps?

Mr. FINLAY: That is what he said in evidence. It is a letter in which he referred to the experiments with charred paper for filaments, and he said that within the last six months he had entirely overcome the difficulties which formerly stood in his way. In evidence he tried to explain that it referred only to the pumps, but what I submit is that putting that together with the fact that three weeks afterwards he took out the patent for the cardboard conductors, and the inference is irresistible that Heaviside is right that before November, 1879, he saw the slender carbon conductors made out of paper. With regard to the third point, the thread, I call attention to the ambiguity of the thread lamp. If by that the Attorney-General means a lamp with a slender carbon conductor, I say that he is proved to be wrong. If he means that a carbon conductor was made out of thread, then I say Swan is very

Digitized by Google

clear that he never used thread to make a carbon conductor until February, 1880. The evidence is practically supported by the cross-examination.

The ATTORNEY-GENERAL: I have to go back to my own argument, and it is somewhat difficult to shorten it. It is quite wrong to suggest that although they saw the horseshoe fine conductor that they saw the thread before it was carbonised. Swan had no exhausting or Sprengel pump, and the exhausting was done by Stearn. I am justified in saying that, so far from F J B 1 being a combination to produce a lamp, it was adandoned by the people who knew anything about it, and it was only unearthed for the purpose of anticipation. Mr. Finlay says all that gentleman has done is to take a combination like F J B 1 and to make a slight modification; but my answer is that F J B 1 led people astray. Then Mr. Finlay said we shall prove that before November, 1879, F J B 1 developed into thread lamps, and they called Proctor and Heaviside to prove that prior to Edison there were thread lamps. So far from their being told nothing by Edison's enunciation of his patent it was the one thing which made every other lamp a success. I say that F J B 1 was absolutely nothing before Edison's invention, and, therefore, I say that Edison's invention was one of enormous merit.

LORD JUSTICE COTTON: Do both sides take these letters between Swan and Stearn as a compendious statement?

The ATTORNEY-GENERAL: I do not think that objection could be made to them now.

LORD JUSTICE COTTON: My brother Lindley says that the letters are admissible as to what was done by Stearn and Swan.

Mr. FINLAY: When they were asked to call Swan and Stearn Sir Horace Davey withdrew his objections to the letters being put in. What I demur to is their being accepted as a compendious statement.

The ATTORNEY-GENERAL: What that correspondence proves is that if they had been working at the carbonised papers with a view to a patent they would have been forestalled by Edison's publication. Mr. Swan had noticed the statement in *Nature* as to Edison adopting carbon, and he wrote that years ago he had used paper in the shape of a horseshoe, and that within the last six weeks he had conquered the difficulties, and produced a perfectly durable incandescent lamp. Now, was it conceivable that if Mr. Swan had shown Heaviside and Proctor hundreds of paper lamps, he would not have referred to that? In February, 1880, their lordships would find that platinum caps were still being used, but nothing was known of Mr. Edison's invention more than was disclosed in the *Daily News*. The Attorney-General hoped that the correspondence had demonstrated to their lordships that anything like a trial of thread had never entered Mr. Swan's mind up till now.

LORD JUSTICE BOWEN: There is this qualification—supposing a hairpin is a filament, the hairpin seems to have worked.

The ATTORNEY-GENERAL said that no one hairpin had worked. It was never published prior to the 10th of November, 1879, and not suggested, unless his opponents could prove Heaviside and Proctor. He contended that the hairpin was not a filament.

LORD JUSTICE BOWEN: You say it was not successfully used before November, 1879, and not then successfully used in fact.

The ATTORNEY-GENERAL said that Proctor and Heaviside were asked about horseshoe lamps, but their lordships would find that there was no suggestion of hairpins being seen by them; but the whole point with regard to their evidence was that they made a mistake of a year. Then he came to the account communicated to *Scribner* by one of Edison's men, and that article described the difficulty as being that of getting a conductor that would bear the intense heat of the current. Lampblack had been found to contain air, which interfered with success. Then Mr. Edison used a simple thread which he found to answer the purpose. He would call their lordships' attention to the House of Lords' judgment that, if a thing be taken and improved, improvements being the only alteration, that invention had been pirated.

LORD JUSTICE COTTON said that that was not disputed.

The ATTORNEY-GENERAL continued that he would demonstrate that every lamp since made, except Bernstein's, had Mr. Edison's new combination, and that every lamp made for multiple arc lighting had it. For days their lordships had been addressed from the point of view that it was not the 1879 specification that made a useful lamp, but what came afterwards that made it. Within a few weeks of commencing Mr. Swan succeeded with thread lamps, and brought out his parchmentised thread patent. The date of these lamps was proved by alterations to the Otto gas engine, which ran them.

LORD JUSTICE BOWEN: Which lamps?

The ATTORNEY-GENERAL: Any thread lamps.

LORD JUSTICE COTTON: The great advantage of these filaments is that there is not heat sufficient to melt the connections or heat the glass.

The ATTORNEY-GENERAL said that was so, and it was stated in the patent. As to lamps having large wires and suitable glass, no use of them had been proved, but only a theoretic opinion given. Sir Frederick Bramwell had been asked as to the advantage of a small filament, and had replied that it lay in enabling the size of the mains for domestic lighting to be reduced. Asked when he first made a thread lamp Mr. Swan said certainly not before 1880, and he thought towards the middle of the year. Mr. Finlay had endeavoured to show that there had been no change in electric lighting in consequence of Edison's combination, but Swan had abandoned the work of years for it, and in a few weeks found success. The question was, when was the step in advance made? The fact of houses being lighted in 1880 by Mr. Swan's lamps showed the extraordinary step in advance made by Edison's combination. It was to be noticed that when they began to use thread lamps they carbonised for themselves, and that further showed the enormous step—the courage of the step to take a thing like thread for a carbon. The merit of Edison's combination was that he swept everything previously known aside. The infringers came and said they knew it all before, and all that it was necessary to do was to diminish the size of the stick in F J B 1, but Edison told them to bend and then carbonise. The vibration of the filament noticeable in Edison's lamp could not be attained by anything made from Carré's carbon. He took the infringing lamp and found it had the vibrating qualities. Edison brought the word "filament" into the electrical art, and no conductor was a filament unless it had the properties of Edison's conductor before it was carbonised. What fresh fact could his learned friend show to prove that F J B 1 was a filament?

LORD JUSTICE LINDLEY: What is the thing in F J B 1?

The ATTORNEY-GENERAL said it was a pencil. It was essential to a filament that it could be taken, twisted and twirled, before carbonisation, and the best description of "filament" was to be found in the specification itself: "Any fibrous, vegetable substance that will leave a carbon residue after heating in a closed chamber." He said that filament meant what Edison described.

Mr. FINLAY: What is it?

The ATTORNEY-GENERAL: "Filament" was so entirely connected with Edison's invention that it had become a common word for conductor, and every single lamp of the millions now used in multiple-arc lighting were Edison's combination. Improvements cheapened the lamp and made it more successful, but no one suggested that the improvements caused the lamp to succeed where it had been a failure—he was referring to subsequent improvements. If it were right to describe F J B 1 as a filament, he did not know why his learned friends could not rely upon King, of 1845, as an anticipation. Bernstein's was said not to be an infringement because of the elastic joint put in to get over the difficulty, which Edison got over in another way. Bernstein had altered the mode of attachment on the one crucial point where every other lamp followed Edison. The definition of a filament was something that could be wound round and round a bobbin, and F J B 1 could never approach to doing that. He asked their lordships seriously to consider what the invention was, and as to minor details of insufficiency of specification he would endeavour to point out that they were as unworthy an attack on a specification as were ever made.

The learned counsel had not concluded his speech when the Court adjourned until Thursday.

(Continued on page 227.)

PARLIAMENTARY INTELLIGENCE.

HOUSE OF COMMONS.—THURSDAY, DECEMBER 20.

ELECTRIC LIGHTING.

Mr. WATT asked the President of the Board of Trade whether the Electric Lighting Act of 1882 precluded the Board of Trade or local authorities from granting licenses to one or more persons, firms, or companies to light the same area; whether the Act contained restrictions as to the breaking up of any street without the written consent of the Board of Trade; whether inquiries are made by the Board of Trade as to the ability of undertakers to carry out the work before licenses are granted; whether he could state what number of licenses had been granted since the last return was issued; and whether it was a fact that the reason assigned by companies which obtained licenses under the Act of 1882 for abandoning these was the enormous law costs which would have been incurred owing to the opposition of the local boards or councils.

Sir M. HICKS-BEACH: The Electric Lighting Act, 1882, does not preclude the granting of licenses to one or more persons, firms, or companies to light the same area. With reference to the second question, the Board of Trade cannot give power to break up streets except under a license or provisional order. As regards the third question, inquiries such as those suggested by the hon. member are made by the Board of Trade. Two licenses have been granted since the last report to Parliament. In reply to the last part of the question, I have to say that no such reason as that referred to by the hon. member has, to my knowledge, been assigned for the abandonment of licenses.

Mr. ROWNTREE asked the President of the Board of Trade whether his attention had been called to notices given for supplying electric light in the parish of Kensington, under the Electric Lighting Acts 1882 and 1888, by the four following companies, viz., the Kensington and Knightsbridge Electric Company (Limited), the Chelsea Electricity Supply Company (Limited), the Notting-hill Electric Lighting Company (Limited), and the House-to-House Electric Supply Company (Limited); whether he was aware that the said companies proposed to conduct their operations mainly, or very largely, within the same area, and in many instances to take power to break up the same streets, roads, or places; whether it was the duty of the Board of Trade, before making any provisional order, to take cognizance, of its own motion, of such *primâ facie* objections; and whether the Board would not take any cognizance unless and until it was moved thereto by the local authority, or other parties interested.

Sir M. HICKS-BEACH: The answer to the first three questions of the hon. member is "Yes;" and the answer to the last is, that it is the duty and practice of the Board of Trade, in framing a provisional order, to consider any objections to which their attention is called, and also any such as may occur to them.

Society of Arts.—On Wednesday evening, January 2nd, at 7 o'clock, Prof. Henry E. Armstrong will give the first of his two juvenile lectures at the Society of Arts, entitled "How Chemists Work: an Example to Boys and Girls

CHRISTMAS GREETINGS.

It has long been the custom of this journal at Christmastide to offer good wishes for the year that is to come, often, however, with small encouragement from the events of the year that was just expiring. No such check to our hopeful view of the immediate future has occurred during the past twelve months, and we can face the New Year with a cheerful confidence which it has rarely been our good fortune to experience. That our readers will share these sanguine anticipations we have very little doubt, and that they have good reason for doing so will be made plainer before we have concluded our review of the year 1888, as we hope to do in the course of the next two or three weeks.

Last Christmas we took for our text the proceedings of the Bradford Corporation with reference to the lighting by electricity of that important industrial centre, marking, as the incident did, a clear and decisive advance in the growth of electric lighting industry. At that time the Act of 1882 had not been amended, and its prospects in the ensuing Parliament remained still in uncertainty. The local authorities determined, notwithstanding, to establish the new light, and their discussions were characterised by an intelligence and sound judgment which augured well for the competence of such bodies to deal with the subject whenever it might be taken seriously into consideration. Since that time numerous municipalities have either followed the example of the Corporation of Bradford or have accepted independent proposals to establish central lighting stations, and on the whole there is much reason, so far,

Digitized by Google

to be satisfied with the general result. In still more numerous instances the question has been under discussion, and where it has been debated without partisan bias, or the opposition of some vested local interests, it has met with a candid and even cordial reception; and where its opponents have carried the day it has evidently been in the face of an advocacy before which they will sooner or later have to yield.

If we were in need of another text for this present Christmas, the installations now in progress at the West End of London would afford an even more encouraging topic for comment. Under the impetus, or rather with the removal, of restrictions, afforded by the passing of the Electric Lighting Amendment Act this year, a number of provisional orders are already being proceeded with, and a great portion of what may be called the best part of the metropolis, including the West, West Central and Central areas, is being rapidly appropriated. Although the decision has come rather late, the Board of Trade have been well advised in declining to grant licenses for the metropolitan area. Complications with the local authorities will thus be avoided. Details of the schemes referred to need not be repeated here; but we may say in a general way that the selection of those districts seems to have been highly judicious for the purposes of a beginning. The localities just mentioned embrace the richest residential parts of London and the best of its shops. Whatever uncertainty may still remain as to the cost of electric lighting as compared with gas, there has never been any doubt about its superiority, or about the willingness of those who can afford it to pay for it as a luxury. If it succeed, as unquestionably it must, in the West, its extension to the East is only a matter of time.

In several other directions not affected by Acts of Parliament the electric light has been making great strides. To say nothing of private installations, which have spread beyond counting, its adoption on board the steamships of the Royal and Mercantile navies has become almost universal—so much so that as regards the former a new appointment has had to be made of superintending technical officer for electric lighting purposes to the Royal dockyards. In other public departments—notably in the Post Office—the same progress is visible, and probably will soon be followed by a similar step. The advance made in perfecting the machinery and appliances connected with this new industry has fully kept pace with its requirements; and under the stimulus of its activity, and the fuller experience gained by its extension, the best types of machinery are gradually being developed, and the manufacture of the lamps simplified and cheapened. These improvements will tend to make electricity a less expensive and more reliable agent in public lighting than it has yet been universally credited with being, and will speedily establish it in the position it is entitled to occupy.

Although the electric lighting business, from the magnitude of its operations, naturally takes a foremost place in our thoughts at present, it is very far from being the only electrical industry which offers subject for congratulation at this moment. Electric traction will soon no doubt make good its pretensions to compete with horse-power and steam; and in several other directions there are signs that electricity as a mechanical agent of great utility and handiness will soon find plenty of employment. Electric lifts and electric cranes are not, strictly speaking, novelties; but their practical application on any considerable scale may be said to be a new and encouraging feature of the times. A striking illustration of the unexpected developments which may be looked for in the near future is furnished by Prof. WHEELER'S electric fire engine, the power being obtained from a motor to be attached to the nearest electric light wire. We may rest assured that this is not the only mechanical use for which the current will be enlisted when the conductors are in full working order. The Telephone Companies have equally good reasons to be gratified with the progress they have been making and the position they have now attained in public estimation. Except, perhaps, in the manufacture of wire and apparatus for shipment abroad, electrical industries of all kinds in this country are vastly improved, and, with the general revival of trade which the highest authorities are agreed in predicting, the coming New Year presents a brighter countenance than she has assumed for a long time past. All this is good cheer, and it has, no doubt, contributed to help our readers to the enjoyment of a merrier Christmas than usual. We wish them also a happier New Year.

GALVANISED IRON LINE WIRE.

The iron wire which is now obtained by the Postal Telegraph Department for line purposes is of two qualities, known as low-resistance and high-resistance wire. The low-resistance wire may consist either of "special blend" iron, giving a mean resistance of 11·3 ohms per mile at 60° F. for the standard gauge of 171 millimetres; or of "charcoal" iron, giving under the same conditions a resistance of 11·2 ohms per mile. The high-resistance wire of the same gauge has a mean resistance of 12·7 ohms per mile.

As, owing to its high price, copper wire is not for the present to be supplied for the service, the low-resistance iron is employed wherever copper wire would otherwise be used; in fact, speaking generally, for all circuits exceeding 200 miles in length. High-resistance wire is employed for circuits not exceeding this length, but systematic use of copper wire for telephone circuits is still continued.

Both qualities of wire are about equal as regards tensile strength, which, as will be seen from the table given below, is somewhat greater than that of the wire hitherto supplied.

The following particulars relating to iron wire will often be of use:—

The relative resistances of pure copper and Swedish charcoal iron, similar to that used for the best line wire, are as—

$$1 : 6{\cdot}034,$$

or the resistance of commercial iron is 6·034 times that of pure copper, not 6·558 times, as usually given in text-books.

The specific resistance, or the resistance in absolute C.-G.-S. units of a centimetre cube at 60°F. is as follows:—

Silver	1609
Copper	1642
Pure iron	9753·5
Commercial iron.....	9907 (instead of 10,769).

From this it appears that iron wire may now be obtained having a conductivity of 98·44 per cent of pure iron.

When the resistance (r) of a sample of iron wire at t°F. is known, its resistance (R) at any other temperature t_1° may be found from the following formula:—

$$R = r\,(1{\cdot}0027)^{t_1 - t}$$

or, for degrees centigrade,

$$R = r\,(1{\cdot}0048)^{t_1 - t}$$

For example:

If a sample of wire has a resistance (r) of 10·99 ohms at 68°F., its resistance (R) at 86° may be obtained thus:

$$R = 10{\cdot}99\,(1{\cdot}0027)^{86-68} = 10{\cdot}99\,(1{\cdot}0027)^{18}$$

$$\log 1{\cdot}0027 = {\cdot}0011710$$
$$18$$
$$93680$$
$$11710$$
$$\cdot 0210780$$
$$\log 10{\cdot}99 = 1{\cdot}0409977$$
$$1{\cdot}0620757 = \log.\ \text{of } 11{\cdot}54$$

GALVANISED IRON LINE WIRE.

Gauge No.	Weight per mile.	Diameter.	Breaking Weight.			Elongation per cent.			No. of Twists in 6 inches.		
			Low Resistance.		High Resistance.	Low Resistance.		High Resistance.	Low Resistance.		High Resistance.
			Blend.	Charcoal.		Blend.	Charcoal.		Blend.	Charcoal.	
	lb.	inch.	lb.	lb.	lb.						
4	600	·209	1,920	1,725	2,100	16-17	16-17	17-18	17	18	22
7½	400	·171	1,280	1,150	1,390	,,	,,	,,	23·5	25	30
10½	200	·121	640	575	695	,,	,,	,,	30	31	38

The required resistance is therefore 11·54 ohms.

1 foot-grain of pure iron has a resistance of 1·097 ohm.
1 metre-gramme of pure iron has a resistance of ..... 0·7654 ohm.
1 ohm-mile of pure iron weighs ..... 4368·94lb.
1 ohm-mile of low-resistance blend wire weighs ..... 4520 ,,
1 ohm-mile of low-resistance charcoal wire weighs ..... 4480 ,,
1 ohm-mile of high-resistance wire weighs 5080 ,,

and, knowing the ohm-mile of any iron wire (which is found by multiplying the weight in pounds per mile by the resistance per mile), we readily get the percentage of conductivity of that wire.

For example, suppose one mile of wire weighing 400lb. has a resistance of 11·2 ohms, then an ohm-mile will weigh—

$$11{\cdot}2 \times 400 = 4{,}480\text{lb.}$$

and its conductivity per cent. will be—

$$\frac{4368{\cdot}94 \times 100}{4480} = 97{\cdot}51.$$

The above table gives the mechanical qualities of iron wire.

ON THE EXISTENCE OF AN UNDULATORY MOVEMENT ACCOMPANYING THE ELECTRIC SPARK.*

BY ERNEST H. COOK, D.SC. (LOND.), F.I.C.

1. If a powdered substance be scattered over a smooth plate, and the plate held near a pair of terminals between which an electric spark is passing, the powder will arrange itself in a more or less regular series of concentric circles. The common centre of these circles (when the spark is small) appears to be a point directly under that halfway between the terminals. The general appearance presented by these curves will be apparent by a glance at the figures in the plate which accompanies this Paper. These are approximately of the same size as the original. It will be noticed that the figures roughly divide themselves into two classes—(1) those with a clear space in the middle, and (2) those with a circular space, within which the powder is apparently unaffected.

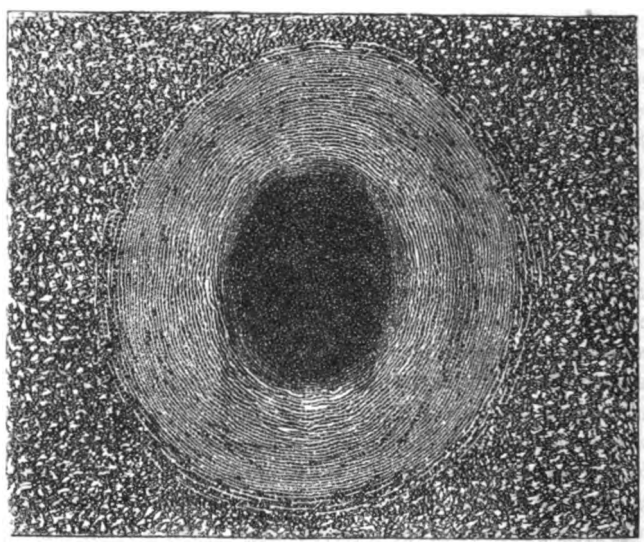
The first class are obtained by holding the plate near to the terminals, the distance varying with the energy of the spark. The cleared space is irregularly elliptical, with its major axis at right angles to the direction of the spark, and the area of the space increases as the intensity of the spark increases. The second class are formed when the distance between the spark and plate is increased until the elliptical space ceases to make its appearance.

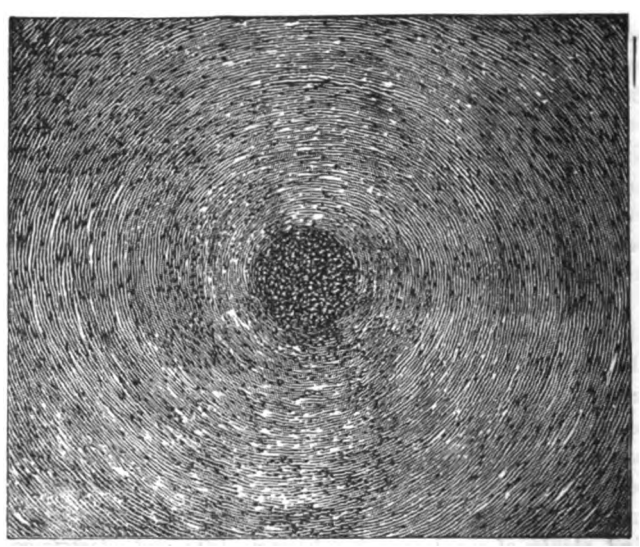
2. *Mode of Obtaining the Curves.*—The most convenient arrangement and the one which gives the best results is as follows :—An induction coil has each of its terminals connected with a Leyden jar, and with one of the handles of a universal discharger. The plate with the powder scattered over it from a sieve is held under the points at a distance which can be varied at pleasure. The distance between the terminals, and therefore the length of the spark, can also be easily adjusted. On connecting the coil to the battery a succession of sparks of condensed electricity is obtained, and the powders will be seen to arrange themselves in the manner described. The first spark causes a distinct effect, but a continuance is necessary to bring out the regularity of the curves.

Should it be required to fix the powders in the positions which they have taken up, it is easily done by coating the plate beforehand with a thin layer of gum, and after the experiment breathing on it.

* Read before the Physical Society, June 23rd, 1888. The Paper was illustrated by a series of photographs; from two of these the figures in the engraving have been taken.

3. *Effect of Plate.*—When the figures were first obtained it was surmised that they might be caused by the distribution of the electricity over the plate; that they were, in fact, modified Lichtenberg's figures. Experiments were therefore made with plates of various substances in different states as regards their surfaces; for example, whether polished or dull, electrified or unelectrified. The following materials have been examined :—Glass, resinous cake of electrophorus (a mixture of shellac, resin, and Venice turpentine), ebonite, paper (glazed and unglazed), brass (lacquered and unlacquered), zinc, iron, tinned ditto, galvanised ditto, wood, paraffin, cardboard, and glazed and unglazed earthenware. Except that the rougher surfaces retard and prevent the regularity of the curves, no difference whatever could be observed as due to the substance or condition of the surface.





A piece of plate-glass, or polished sheet of metal, answers admirably for these experiments. The fact that the production of the curves is independent of the electrical state of the support (and therefore of the powder) justifies the statement that they are not caused by any peculiarity of electrical distribution.

4. *Effect of Battery Power, Coil, and Condensation*—Experiments were made with the view of finding if variations in the number of cells, in the coil, and in the capacity of the condensers used, caused

Digitized by Google

any alteration in the shape or frequency of the lines in which the powders arranged themselves. Other conditions remaining constant, the battery power employed to drive the coil was changed from ten-pint bichromates to one. In no case could any difference be observed in the resulting figures produced. Afterwards the current was still further reduced until it was just sufficient to drive the coil, but so long as this was accomplished the figures remained unaffected.

Several coils were used in the course of the earlier experiments, but finally the work was confined to two. One of these was a very fine instrument by Ruhmkorff, kindly lent to me for the purpose of these experiments by Mr. Francis J. Fry, late high sheriff of Bristol. It contains a secondary coil, formed of twenty-four miles of wire, is fitted with both spring and mercury interrupters, and with one bichromate (carbons 7in. by 3½in.) gives a regular succession of sparks 6in. long. The second was a smaller instrument, by Paterson of London, fitted with a condenser of 100 sheets of 12in. by 5in., and capable of giving a small spark of about 1½in. long. When coupled with the Leyden jars, of course, the length of spark was much diminished. In no case with either coil was a longer spark employed than ·75in. No change in the appearance, regularity, or shape of the figures was caused by replacing one coil by another.

The effect of a difference in condensing-power was tried by interposing more jars. Except that the vigour of the spark caused a larger area of cleared space, no alteration could be observed. This is, of course, confirmed by the fact of the different coils, possessing condensers of different areas, giving identical results.

5. *Influence of Contact-Breaker.*—It might be supposed, as was done by Grove in reference to the stratifications in partial vacuo, that the intermittent character of the currents flowing in the secondary wire caused by the interruptions in the primary-coil by the contact-breaker would have some influence in producing or regulating the curves. This, however, is not the case. The shapes did not alter no matter what coil was employed, and when the mercury-break on the large coil was used in place of the spring no alteration in the resulting curves was produced. Moreover, the curves can be obtained without the use of a coil with its necessary contact-breaker at all. For this purpose it is only necessary to connect each electrode of a Wimshurst machine to one or two Leyden jars, and to allow the highly condensed spark thus obtained to act upon the powder; in fact, I have been able to produce the curves in this way without employing any jars at all. With the machine, however, they are far inferior in regularity to those produced by the use of the coil. With a 17in. plate the best results have been obtained with jars having a total area of foil of about 1,500 square inches, a spark of about 3in. long, and the powder 6in. below spark.

6. *Nature of Electrodes.*—Varying the material forming the points between which the sparks were taken made no difference in the resulting shapes. Thus the same effects are produced by using brass, iron, or carbon points.

7. *Influence of the Powdered Substance.*—Soon after the first results were obtained, and upon trying different substances, it became evident that, although accidental irregularities occurred, yet, upon the whole, the curves were remarkably regular. It was also very soon noticed that the frequency with which they followed each other altered with an alteration of the substance of which they were composed. This induced a desire to compare by measurement the distances between each successive curve. A large number of different powders were examined, and the number of lines in a certain distance counted. Several determinations were made and the mean number taken. Although every care was taken to make these measurements as accurately as possible and to avoid sources of error, yet, from the difficulties peculiar to the case, I do not wish to pledge the absolute accuracy of the numbers, but put them forward as approximate only. It first became necessary to ascertain if the fineness of the powder affected the number of lines in a certain length. This was found not to be the case. Provided the degree of fineness was such as to admit of the production of the lines with such an amount of definiteness as sufficed for their measurement, the number of lines was found to be unaltered. The following tabular statement gives the results obtained. The actual experiment was to count the number in a quarter of an inch. These have been multipled by 4, hence the regularity of the diminution of the numbers given in the first column:—

No. of Lines in 1 inch.	Substances Examined.
88.	Silica (powdered sand).
80.	Magnesia alba.
68.	Chromic oxide.
64.	Antimony sulphide; baric peroxide; fluor spar; cupric oxide; red lead; lead acetate; lead oxide; antimony; sulphur; potassium hydrogen tartrate.
60.	Borax; cobaltic oxide; starch; zinc carbonate.
56.	Binoxide of manganese; baric carbonate; tricalcic phosphate; ferrous sulphide; lead chromate; mercuric oxide; binoxide of tin; nickel monoxide; lead carbonate; calcic oxide.
52.	Sodium hydrogen carbonate; potassic sulphate; potassic carbonate; mercurous chloride; carbon; calcic hydrate.
48.	Tannin; salicylic acid; rochelle salt; ammonic sulphate; baric nitrate; copper sulphate; oxalic acid; sodic chloride succinic acid; Epsom salts.
44.	Alum.
40.	Chalk.
The figures were so indefinite as not to permit counting.	Iron filings; baric chloride; baric sulphate; benzoic acid; strontium chloride; bismuth nitrate; cadmium nitrate; microcosmic salt; potassium chloride; potassium bromide; ammonium chloride; ferrous sulphate; ammonium nitrate; pyrogallol.

8. *Effect of Mixture.*—While engaged in repeating the experiments, in order to confirm the numbers, it was found that a particular sample of calcic oxide gave 48 lines to the inch instead of 56, as given in the table. Upon examining the sample it was found, however, to be an old one, and to be partially converted into carbonate. It was thus a mixture of oxide and carbonate. This led to the investigation of other mixtures. It was thus proved that the number given by a mixture of two substances was intermediate between those of its constituents. The following were examined, no particular care being taken to mix in definite proportions, but the substances simply ground up together in a mortar:—

Mixture.	Nos. due to each constituent.	No. obtained.		
		Exp. 1	2.	3.
Calcic oxide	56	48	50	48
Calcic carbonate	40			
Magnesia alba	80	60	64	56
Calcic carbonate.....	40			
Cobaltic oxide	60	64	64	66
Chromic oxide	68			
Cobaltic oxide	60	68	64	68
Magnesia alba	80			

9. *Effect on Liquids.*—In order to test if the effect could be produced on the surfaces of liquids the following experiments were made:—In place of a glass plate with the powder scattered over it, there was held under the spark a shallow vessel (an ordinary porcelain evaporating dish answers very well) containing the liquid. So long as the surface was looked directly down upon, no effect could be observed; but when regarded obliquely, minute ripples were seen to be produced upon the surface. No attempt was made to measure these, but they were judged to be of about the same size as those of the powders—that is, between the limits of 88 and 40 to the inch. The following were the liquids tested in this way:—Water, mercury, alcohol, ether, glycerine, and benzol.

10. *Experiments with Wimshurst Machine.*—It has already been stated that the curves obtained by the aid of the machine are much inferior in regularity to those given by the induction coil; in fact, without care they cannot be produced at all. But there are some other peculiarities which deserve notice Thus, while with every coil used, and with varying battery-power, it was found that magnesia alba gave 80 lines to the inch, when the machine was used the number varied in different parts of the figure from 56 to 64. There was no particular mode of variation—that is, no crowding together at a special place, &c. This irregularity in the numbers is not, however, a general thing, for in other cases tried the numbers did not vary among themselves and agreed with those obtained with the coils.

The common centre of the circles, instead of being, as with the coil, half way between the terminals, seemed to be a little nearer the positive electrode than the negative. Other experiments are, however, necessary before this can be regarded as established.

In experimenting with this machine it is necessary to avoid placing the plate too near the terminals, otherwise the powder becomes electrified, and the plate also, and the resulting figures are combinations of those showing the distribution of the electricity upon the plate, and the undulatory effect discussed in this Paper.

Most of the figures obtained with the machine were caused by the spark passing between knobs. They are imperfect at the sides in consequence of the undulatory effect being prevented from making itself felt in those directions by the solid body of the knob coming between. Thus the portions of the circles shown are at right angles to the direction of the spark. The figure can of course be obtained from sparks taken between points, but it is more difficult. It was particularly noticed in the course of these and some other experi-

Digitized by Google

ments that, whilst substituting a knob for a point in a Wimshurst or other machine increased the length of spark obtainable, it was just the opposite with a coil, for here the spark is considerably reduced if taken between *two* knobs. The longest spark with a coil is obtained either between two points, or between two points, or between one point and one knob or plate.

It was also noticed that under the positive electrode the powder was scattered so as to cause a space. This is sometimes, but not always, the case under the negative.

11. *Production of the Cleared Space.*—It will be observed that the more or less elliptical space in the middle of the figures is not present at all. It is only produced when the plate is held close up to the terminals, and when the vigour of the spark is considerable. At a first glance at a figure containing the clear space, it appears that the lines are crowded together at the ends of the major axis of the ellipse. Closer examination and careful measurement will show, however, that this is not the case, for the number of lines per unit of length is the same whether measured at the ends of the major or of the minor axis; in fact, the appearance is just that of concentric circles, formed of the powder, with the material composing the smaller circles swept up so as to form the irregular ellipse.

From this fact, and also that the circles can be produced without any clearing of the powder, I am led to conclude that the production of the circles is due to *an entirely different cause* to that producing the space, but that both are necessary accompaniments of the disruptive discharge.

12. *Discussion of Results.*—When these figures were first obtained it was imagined that they were due to the sound which accompanied the spark, and in fact gave a graphical representation of the sound-waves. This view was to some extent confirmed by finding that the same substance gave the same number of waves in the same space. If this be so, however, then there ought to be no difference in the numbers obtained with different powders; for the sound of the spark produced by a coil is remarkably constant, and, if such a term can be rightly applied to it, it is of unvarying pitch. This view, however, is also disproved by the measurements; for if it be taken that the lines show the phases of the undulatory movement, then the longest distance between similar phases is that given by powdered chalk, viz. $\frac{1}{40}$ of an inch. But the upper limit of vibration producing a sound-wave may be taken as equal to 40,000 per second, giving a length for the wave of as nearly as possible one-third of an inch, a distance thirteen times greater than the longest given by these experiments. It is therefore evident that the vibrations producing these curves and those producing the sound of the spark are not identical.

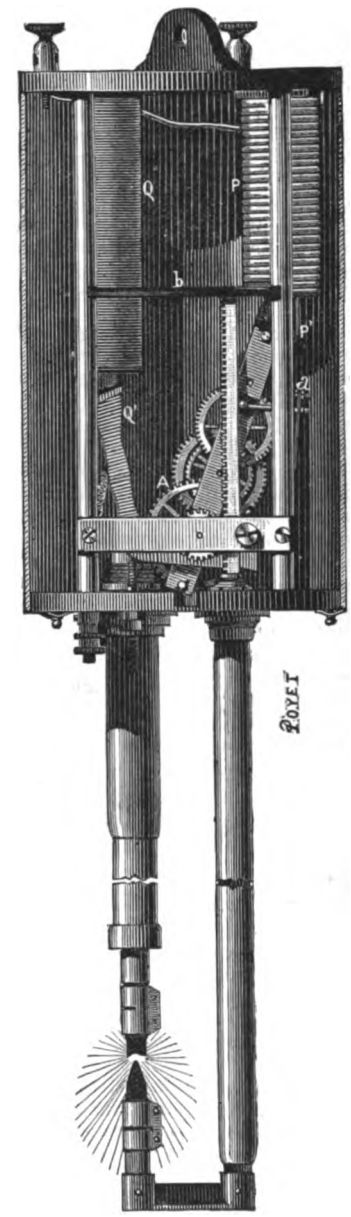
From the fact that the number given by a mixture is intermediate between those of its constituents, we should be led to conclude, since the density of a mixture follows the same law, that therefore this is the factor which regulates the number given by any particular substance. If this be the case, then the powders should arrange themselves in a series, with those of the highest density at the top and those of the lowest at the bottom. A glance at the tables of results will, however, show that no such order is observed. Thus we have silica giving a higher number (88) than the heavy oxides of lead (64); magnesia alba, a substance of very low specific gravity, appearing high up in the list; and tannin, also of low specific gravity, on the other hand, appearing low down. What conditions, if any, regulate the number of these lines I have hitherto been unable to determine. Before any generalisation can be made it is necessary to examine a very much larger number of substances, and experiments are being conducted with this purpose. At present, indeed, I am not disposed to attach much importance to the absolute length of any one of these undulations, but rather to the great similarity of the measurements as a whole. For although it is likely that errors may occur in some of the individual members, it is hardly possible that the whole are erroneous. It will therefore follow that undulations of a length of about one sixty-fourth of an inch (taking the mean measurement) accompany the disruptive discharge.

The photographs from which the figures in the plate are copied were taken for me by Mr. Dunscombe, of Bristol, and were printed from the negatives without the latter being touched in any way.

Note, June 9, 1888.—Since the above was written, I have been informed by Prof. Rücker that he has an apparatus in his possession, made by the late Dr. Guthrie, which gives somewhat similar results. This was copied from one exhibited at the Loan Exhibition of scientific apparatus in 1879. It consists of an elliptical dish with vertical walls. Sand is scattered over the bottom, a glass plate placed over the top, and a series of electric sparks produced at one focus of the ellipse. The sand will then be found to arrange itself in a series of circular curves around the other focus. The curves thus produced bear a striking resemblance to those exhibited in the plate accompanying this Paper, and are of course due to the same cause.

THE PUYDT ARC LAMP.*

In this apparatus the descent of the rod of the upper carbon holder supplies the motive power. This rod gears into the wheel A, which forms the first of a series of toothed wheels mounted on an oscillating frame. The upper end of the lower carbon holder gears into a second wheel, which is on the same axis as A. These two wheels are so proportioned that the arc remains fixed while the lamp is in operation. The striking of the arc is effected by means of the electro-magnet P, which is in series with the arc, and which acts upon an oblique armature P', connected to the frame of the



The Puydt Arc Lamp

clockwork; P', when attracted by the electro-magnet, causes this frame to revolve round its lower axis, thus forcing the carbons apart. The length of the arc is regulated by the electro-magnet Q, which is a shunt upon the arc, and whose armature Q' is fixed to an U-shaped lever, revolving upon the same axis as the frame of the clockwork. This lever terminates in the brake *a*, which clutches or frees the last wheel of the series. An easily regulated spring brings the lever back to its normal position whenever the current is interrupted. This lamp is made by M. Jaspar, of Liège. Its mechanism is more simple than it appears to be from the description, and good results are obtained in practice.

Edison and Swan Electric Light Company v. Holland and Others—(*Continued from page 221*).

THURSDAY, DECEMBER 13.

The ATTORNEY-GENERAL resumed his address, and, handing the 500 candle-power lamp to their lordships, pointed out that it had two small wires run through instead of one, and said that as long as Swan and Stearn used thick wire they had fractures.

LORD JUSTICE LINDLEY: As I understand you, if you have these thin wires you can be quite indifferent about the glass?

The ATTORNEY-GENERAL: Quite so. One installation at Middlesborough was the only one referred to by a witness as being run in series; and their lordships would not forget that Mr. Justice Kay had founded his decision on the assumption that series was as useful as multiple arc lighting. The transformer system, as far as this trial was concerned, had no existence. Further, Sir Frederick Bramwell had said with regard to the F J B 1 that the pencil in that had been made after carbonisation, that it was a lamp of extremely low resistance, and therefore unable to accomplish what Edison's lamp did. In 1880 some lamps were sent over by Mr. Edison and placed in the hands of the scientific adviser of the Edison Telephone Company. These were run off galvanic batteries in a room in Queen Victoria-street, being arranged in parallel. Those lamps were exhibited during some weeks, and the only cross-examination upon that was to the point that those were made under the December specification. When he came to deal with the question of the November specification being sufficient he should submit that it was immaterial under which specification they were made. The whole strength of Edison's case was that the defendants could not grapple with the question really, but were obliged to try to fritter it away bit by bit. Even Lane-Fox—a man of great ability in the matter—had used asbestos and other things; and again could be seen the courage of Edison's step in saying, "Take a thread for your carbon and the problem is solved."

LORD JUSTICE LINDLEY asked why F J B 1 was not an infringement?

The ATTORNEY-GENERAL replied because the filament, if it could be so called, was not capable of being twisted. It was an abandoned experiment, and *nihil ad rem*. Continuing, the learned counsel said that he had shuddered (laughter) at one of Mr. Finlay's statements as to tar-putty lamps being worthless, because they did not run any appreciable time, but Mr. Gimingham had made, long before Crookes's experiments, lamps that would run for 150 hours.

Mr. FINLAY: Not those made in the first instance.

The ATTORNEY-GENERAL said it was before Mr. Gimingham was recalled, and long before Mr. Crookes's experiments took place. These lamps were run, but Sir Horace Davey said, "These may be very good lamps, but we are not satisfied they were made according to the specification."

Mr. FINLAY said that it was not until after the cross-examination of their witnesses, at a later stage of the case, that they found out how to do these things.

LORD JUSTICE COTTON said he thought that there was no question about any cross-examination as to the amount of pressure, but he thought that Mr. Finlay had suggested that it had been found out after the commencement of this trial, by experiment or otherwise, that considerable pressure must be used with tar putty filaments.

The ATTORNEY-GENERAL said he would argue that point upon the specification presently.

Mr. FINLAY: Show a single question put by you in cross-examination upon it.

The ATTORNEY-GENERAL said that this was not quite fair; his point was an entirely different one. There were in existence lamps sworn to be made four years before for the Woodhouse and Rawson trial—and if there was any suggestion that those were not useful lamps, why was it not asked to have them run? Boys and girls made those lamps, and it was ridiculous to suggest that they had skilled instructions given them. As to the time occupied in making the tar putty filament, his opponents and Mr. Justice Kay relied upon it being an hour and a-half. The man Plum, of course, would be desirous to work so as not to break down, and took on the first occasion one hour and ten minutes. Now Prof. Stokes had stated that subsequently it was done much more quickly, he taking the time in the presence of Prof. Thompson, and on the other occasion it took seventeen minutes. It had to be rolled out to $\frac{7}{1000}$ part of an inch.

LORD JUSTICE BOWEN: It is the making of the putty that takes twenty minutes, not the rolling.

The ATTORNEY-GENERAL said they were working for a filament, using tar and lampblack, and he asked their lordships to consider the elements of failure. Of course there must be such homogeneity that there would be no piece of lampblack sticking out; if there were a piece not worked in it would come off, and there would be a hole in the filament. His opponents seemed to think that when they had got the putty they had not to go on and make it homogeneous. (The specimens of the putty sent by Prof. Stokes to Mr. Justice Kay and specimens of the materials used were here handed to their lordships.)

Mr. GRAHAM said that the first day he went he noticed that it was done with a great amount of time and labour. That was considered so important that he wrote a memorandum and gave it to Prof. Stokes, and it opened their eyes for the first time to the secret.

LORD JUSTICE COTTON: What we want to know is the fact of the time.

Mr. GRAHAM; Plum set to work next time, and used a much larger amount of energy, and did it in 17 minutes.

Mr. FINLAY: The point is the amount of force—greater force used in a shorter ime.

The ATTORNEY-GENERAL said he would ask their lordships to take the exact parallel of kneading dough. Assume that there were no agglomerations in the dough, assume that Plum worked harder when he did it in the shorter time, and he submitted that this was the most trifling special pleading ever known. The kneading was to be done properly, so that there remained no infinitesimal pockets of lampblack; but it was now contended by his opponents that, because the time of the kneading and the strength to be used were not shown, the patent was incomplete. Suppose the putty broke when rolled out to $\frac{7}{1000}$ part of an inch, could it be said that it had been properly kneaded? Prof. Stokes in his report said that the proper condition of the tar putty was deemed to have been attained, and the required consistence attained as judged by comparison with common putty. He asked their lordships if that was fair? No. It must be tried to be rolled out to do the work the specification said. The experiment was tried in such a way that it must fail. In the next case the report said "a little more lampblack had been added, in this case about a minute and a-half before finishing." He asked their lordships' particular attention to that—they had been working at it for nearly sixteen minutes, and then they added more lampblack. A portion of the putty rolled between the thumb and finger cracked and blackened the fingers; and yet these professors took and used a putty which blackened the fingers and cracked at the ends. It was not properly mixed. Then the report said, "the roll of tar putty on being squeezed became shiny on the suaface, indicating the oozing out of a part of the mixture," and this was said to be a proper mixing of putty that was to be rolled out to the $\frac{7}{1000}$th part of an inch! "An attempt was made to roll it," and the material would not hold together. The respondents contended that this kneading was not properly known until these experiments. How, then, did Prof. Dewar make filaments which would burn? The answer was, that if you tried to work as the specification directed it would do, and if so as to make it fail, it would fail.

LORD JUSTICE BOWEN said he could not help feeling that that would be a fraud.

The ATTORNEY-GENERAL said he considered that Mr. Crookes's evidence was not fair. Water had been used to moisten the putty, and no chemist would have used water. Of course, tar putty could be rolled out, but his learned friends were contending that it ought to be done without even practice. (Specimens of the tar-putty were here handed to their lordships.) The inventor, the Attorney-General contended, was under no obligation to put in the time of the operation. Frankland had produced a filament for the Woodhouse and Rawson trial—it was a Pulvermacher, and that witness in this trial had expressed his surprise at Crookes's failure.

Mr. FINLAY observed that Mr. Justice Kay had said that he had reason to believe that Prof. Crookes carried out the experiments satisfactorily.

The ATTORNEY-GENERAL said that these facts were not before Mr. Justice Kay, and he believed he should show their lordships that the experiments were not as fair as they might have been. Mr. Finlay had said that they only found out about the tar putty after the defendants' evidence had begun, but their lordships would find in Gimingham's evidence there had been no cross-examination as to inability to make the tar putty. Gimingham was called on the 19th of April; the experiments before Prof. Stokes took place on the 11th of June.

LORD JUSTICE COTTON: Does Mr. Finlay say that Gimingham never made tar putty lamps; or that, having made them, he never ran them for duration?

Mr. FINLAY: That he never ran them for duration before this case.

The ATTORNEY-GENERAL said that the secret instructions were nothing more than to knead longer. He asked on what ground was there a failure when the lamps had been proved to burn? In other experiments tar and plumbago were used when tar and lampblack ought to have been, as the specification said distinctly plumbago had silicon in it, which was fatal. As to the iron box used, it was alleged that its size ought to have been in the specification. There was nothing in the use of a small box in place of a large one. The one used was said to fit carefully, but it was agreed that it was common knowledge to pack things to be carbonised with charcoal. Why were filaments to be excluded from that common knowledge? What was the outcome of the attack in the specification? The E G lamps were proved to have been made by Gimingham, and the defendants never examined him as to the impossibility of making one of these lamps. Mr. Justice Kay had said that it was agreed that, if charcoal packing were used, there was no difficulty in the carbonisation. This point of defence was an afterthought. Prof. Stokes stood as a referee, and reported in favour of Edison's experts, and gave reasons for the failures. The Attorney-General asked their lordships to say that the attack on the specification had failed. Tar putty, Mexican fibre, a splint, lancewood splints, and so on—all tried, and not a failure amongst them. Was it a great combination, or was it not? It was as great as any of the very marvellous inventions of Mr. Edison. He asked their lordships to say that F J B 1 was an abandoned experiment. In Edison's specification first appeared the use of the word filament, and he submitted that the appellants were entitled to judgment on appeal. If that were so given he should ask their lordships to hear him as to the form of the order.

Their lordships reserved judgment, it having been arranged for the exhibits to be placed in a room where their lordships could have access to them.

Watt v. The Maxim-Weston Electric Company—The Maxim-Weston Electric Company v. Watt.

On Thursday in last week Mr. Watt, late managing director of the Maxim-Weston Electric Company, made a motion to commit Mr. John Marks to prison for contempt of Court in having made certain statements in a speech delivered at a reconstruction meeting of the company held on the 3rd inst. Mr. Marks was chairman of the meeting. The ground on which the motion was made was that the statements related to the matters in dispute in the

Digitized by Google

legal proceedings pending between Mr. Watt and the company, and tended to prejudice a fair trial. It appeared that a shorthand writer was employed by the directors of the Company at an expense of five guineas to take down what happened at the meeting, and the proceedings were reported, and the obnoxious statements appeared in the report in the *Financial News* and *The Electrician*, and as many as 1,800 copies of the former paper were purchased for distribution by the directors of the company, for which £7. 10s. was paid. The words complained of as reported in the *Financial News* were as follows :—

"He said deliberately that the last balance-sheet Mr. Watt issued to the shareholders was absolutely false. It showed a false profit, on which Mr. Watt had taken 5 per cent. commission. Not only that, but there were sales entered in the books as *bonâ fide*, and which they found were bogus sales, large profits arising from these being shown on the books, but on which in reality the company made a serious loss. Mr. Watt had taken 5 per cent. commission on these. It was Mr. Watt's management, or rather mismanagement, which had brought them to their present position."

Mr. Marks in his evidence asserted that the report was not absolutely correct, inasmuch as he had not charged Mr. Watt with taking, but only with claiming the 5 per cent. commission; but in this his lordship considered Mr. Watt mistaken. At the beginning of his speech he had himself explained that he intended to refrain from going into the matters in dispute because the legal proceedings were pending, and it was in answer to questions, he said, that he was drawn into making the statements complained of, and he claimed privilege. —Mr. Napier Higgins, Q.C., and Mr. George F. Hart appeared for Mr. Watt in support of the motion; Mr. Cozens-Hardy, Q.C., and Mr. Gazdar, for Mr. Marks, opposed. —Mr. Justice North considered it was not a case in which the respondent should be sent to prison, but he did consider it a case in which he had transgressed the rule of the Court, which required parties to abstain from publishing matter tending to obstruct the course of justice. He said that, though Mr. Marks had not himself ordered the employment of the reporter for the purpose of publishing the proceedings at the meeting, he was one of the directors who had acquiesced and was responsible. With respect to the defence of privilege, if it were the case that Mr. Marks would have been justified in making the remarks to his own shareholders in response to inquiries, that did not apply to the publication to the world in the newspapers, and it was not like a case where the remarks got into the newspapers without authority. He therefore ordered the respondent to pay the costs of the motion.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *December 15th*, 1888.

We have had during the past week another series of experiments by Mr. Harold P. Brown, and the medical men previously associated with him, with regard to the effect of currents of electricity on animal organisms. You will remember that Mr. Brown recently rendered himself quite famous by his experiments on several dogs with direct and alternating currents. At that time, although the alternating current proved very effectual with the dogs, the question was naturally raised in some quarters whether it would be as effective with bigger animals. The heaviest of the dogs weighed only about 90lb., and it was argued that a greater E.M.F. would be necessary to kill a human being. This new series of experiments was conducted at Mr. Edison's laboratory, and in this case the horse it was that died. It appears that with the main current of an alternating machine at 770 volts the mare and the two calves experimented upon died immediately, the death being painless, as well as instantaneous. It may be mentioned that the mare, with the halter, weighed 1,230lb.; she had a dislocated hip, but otherwise is reported to have been in good condition. It was first tried to perform the experiments by making the connections around each fore leg, in order to approximate to the condition that would obtain with a criminal held in metal wristlets; but it was proven that the head and spinal column were much better points of application for the purpose of electrical execution. What gave importance to this series of experiments, besides its bearing on the use of alternating currents, which, perhaps, is not a slight one, is the fact that electrical executions are called for by law on capital sentences after January 1st. The Medico-Legal Society of this city is to take up the question this week, at its annual meeting, when reports and Papers on the subject will be presented. In the meantime, I may as well say that I find a not remarkable absence of interest in the subject on the part of electricians, and I think if our profession here were polled it would be found that a large majority would vote against the use of electricity for death-dealing purposes.
